IN MEMORIAM
THOMAS CLEMENT CHENG
NOVEMBER 5, 1930–NOVEMBER 28, 2000

Thomas C. Cheng, an international authority in the fields of parasitology, molluscan biology, and shellfish diseases died on November 28, 2000 in Charleston, South Carolina. He was 70 years old and is survived by three children, Thomas, Jr., Brad, and Allison.

Tom was born on November 5, 1930 at Nanking, China. He moved to the United States with his parents he was six years old. Tom spoke very little English but arrived without any problems and soon attended local public schools. After graduating from Greenbrier Military School, Lewisburg, West Virginia he attended Wayne State University at Detroit, Michigan, with a major in biology. While at Wayne State, he enrolled in a parasitology course taught by Professor Dominc L. DeGiusti and became very interested in the public health importance of parasites. After graduation, he joined the U.S. Army and for four years he worked in a clinical diagnostic laboratory performing parasitology, serology, and bacteriology during the Korean conflict. These experiences triggered even a greater interest in parasites, and upon discharge from military service, he enrolled in the graduate program at the University of Virginia and received his M.S. in biology in 1956, and his Ph.D. in 1958 under the of codirection of Professor Bruce Dodson Reynolds and Professor Horton Holcome Hobbs, Jr.

His first faculty position was at the University of Maryland, Baltimore, Maryland as an instructor-assistant professor. One year later, he joined the Department of Biology at Lafayette College, Easton, Pennsylvania. During his six years at Lafayette College, he taught various courses including parasitology, microbiology, general biology, physiology, and invertebrate zoology. During these six years, he formulated and wrote his first book, *The Biology of Animal Parasites*. The book became a popular textbook for an introductory course in parasitology. He was awarded a National Institutes of Health Fellowship in 1964 to travel to the Pacific Biomedical Research Center at the University of Hawaii, Honolulu, Hawaii. He worked as a visiting scientist on the modes of infection of *Achatina fulica* by the larvae of *Angiostrongylus cantonensis*. After this one-year fellowship, he returned to the U.S. mainland and was appointed Chief of the Immunology and Parasitology section at the U.S. Public Health Service Northeast Marine Health Sciences Laboratory at Narrangansett, Rhode Island. It was here that he started one of his most significant academic accomplishments, the writing of *Marine Molluscs as Host for Symbioses with a Review of Known Parasites of Commericially Important Species* that was published in the 5th volume of *Advances in Marine Biology*.

He then returned to the University of Hawaii to join the Department of Zoology. After five years, he returned to Pennsylvania and created and directed the Institute for Pathobiology at Lehigh University. The next 12 years were very productive and exciting for Tom. However, 1980, Tom was approached by the Medical University of South Carolina and asked if he would be interested in creating a Marine Biomedical Research Program. He accepted their offer and the challenge and joined the Medical University at South Carolina

at Charleston, South Carolina. He served as Director of this program until his retirement in 1993. While the Director of the Marine Biomedical Research Program, he accepted the position as Acting Chairman of the Department of Cell Biology and Anatomy of the Medical University for 18 months. It was during this time that he was recognized by the scientific community for his significant contributions to the advancement of molluscan immunology and host parasite interactions. He received numerous awards including a Senior Fulbright Scholar, Directeur de Recherche Award, and the Montpellier Medal and was in very active in lecturing and chairing many national and international meetings and congresses.

Tom retired in 1993, but still remained active at the laboratory bench working on molluscan diseases and immunology until the end. During his seven years of retirement, he continued to write research grants and gain funding for his ideas. When diagnosed with terminal esophageal cancer, his pace slowed but not his interest in his research. He continued to work daily for several hours until he could no longer fight the fatigue and pain. Tom Cheng was a bright and energetic teacher and scientist who helped shaped the careers of many individuals who worked in the areas of parasitology and molluscan immunology. He published over 350 scientific papers, 22 books, and served as Editor of the *Journal of Invertebrate Pathology* for twenty-three years and twenty years as coeditor of *Experimental Parasitology*. He directed twenty-three graduate students and ten postdoctoral fellows.

The field of molluscan shellfish pathobiology and parasitology will miss Tom Cheng. However, his contributions to these important areas will continue to live through his scholarly works, his students, and colleagues he touched during his remarkably productive life.

ANOTHER INTRODUCED MARINE MOLLUSK IN THE GULF OF MEXICO: THE INDO-PACIFIC GREEN MUSSEL, *PERNA VIRIDIS*, IN TAMPA BAY, FLORIDA*

DEBRA A. INGRAO,[1]* PAULA M. MIKKELSEN,[2] AND DAVID W. HICKS[3]

[1]*Center for Coastal Ecology, Mote Marine Laboratory, 1600 Ken Thompson Parkway, Sarasota, Florida, 34236;* [2]*Division of Invertebrate Zoology, American Museum of Natural History, Central Park West at 79th Street, New York, New York 10024-5192;* [3]*Department of Biology, Lamar University, P.O. Box 10037, Beaumont, Texas, 77710*

ABSTRACT In July 1999, green mussels were seen for the first time at Tampa Electric Company's (TECO) Gannon Station Power Plant (Gulf of Mexico, Hillsborough Bay portion of Tampa Bay, western coast of Florida) during routine maintenance of the seawater intake system. The mussels were identified as *Perna viridis* (Linnaeus 1758) based on shell and anatomical characters. This identification has been confirmed by cytological analysis. *Perna viridis* had previously not been found in the United States or in the Gulf of Mexico. *Perna viridis* is a native species in the Indian and Pacific Oceans and was discovered in the Caribbean Sea in Trinidad in 1990 and in Jamaica in 1998. The populations are widespread locally and well established; the largest specimen collected was estimated to be 15 months of age. This is the second species of *Perna* introduced to the Gulf of Mexico, joining *Perna perna* (Linnaeus 1758), which was discovered in Texas in 1990. Since the initial discovery of *Perna viridis* in Tampa Bay, range surveys have found it as far north as John's Pass in St. Petersburg, Pinellas County, Florida and as far south as Boca Grande, Charlotte County, Florida.

KEY WORDS: *Perna viridis*, Bivalvia, exotic species, invading species, Mytilidae, Florida, aquaculture

INTRODUCTION

The introduction of non-native species through natural, intentional or accidental transport by human activities is a threat to natural flora and fauna and can cause severe economical impact (Meineke 1999). According to Carlton (1992), the major human activities resulting in the introduction of non-native species in North America are the following: the transportation of organisms on the outside (fouling species) or on the inside (boring species) of ships; the transportation of organisms inside vessels in solid ballast (rocks, sand and detritus) or ballast water from coastal, transoceanic, and interoceanic vessels; the transport of oysters (including organisms, sediment and detritus on or in the oyster shells); and the intentional release of species for fisheries purposes. United States coastal and inland waters now support a large list of invasive bivalve species [e.g., *Perna perna*, *Mytilus galloprovincialis* Lamarck 1819, *Dreissena polymorpha* (Pallas 1771), *D. bugensis* Andrusov 1897, *Musculista senhousia* (Benson 1842), *Corbicula fluminea* (Müller 1774); see Turgeon et al. (1998) for full list].

In July 1999, Tampa Electric Company (TECO) requested Mote Marine Laboratory (Sarasota, Florida) to identify "green mussels" that were discovered fouling the water intake structures of TECO Gannon Station Power Plant in the Hillsborough Bay portion of Tampa Bay, Florida (27°54′25″N; 81°25′35″W). The green mussels were immediately recognized as members of the tropical/subtropical genus *Perna* comprised of three extant species: *P. perna* (Linnaeus 1758), *P. viridis* (Linnaeus 1758), and *P. canaliculus* (Gmelin 1791) (reviewed by Siddall 1980a). The three *Perna* species are similar morphologically and exhibit considerable variation in taxonomically important morphological characters (Siddall 1980a; Sadacharan, 1982, Holland et al. 1999), making it difficult to separate the species.

In the past, *Perna* species were easily distinguished from one another on the basis of their mutually exclusive geographical distributions. *Perna perna* occurs natively in warm tropical and subtropical coastal regions of South America and Africa (Jeffs et al. 1999) and also extends into the Mediterranean (Berry 1978). *Perna viridis* is a tropical euryhaline species, widely distributed natively throughout the Indo-Pacific having a western limit from the Persian Gulf, an eastern limit at Papua New Guinea (Morton 1987), and northern limit to southern Japan (Cheung 1993), including southern China (Huang et al. 1983). *Perna canaliculus* is only found in coastal waters of New Zealand (Siddall 1980a) and is found on North, South, and Stewart Islands but is most abundant in central and northern New Zealand (Powell 1979; Jeffs et al. 1999).

Today, these species can no longer be distinguished from one another based only on geographical location. Segnini de Bravo et al. (1998) mention that *Perna perna* colonized the Caribbean Sea several decades ago. Diaz Merlano and Hegedus (1994) report a series of fresh shells found on the beach near Bocachia along the Columbian coast. The geological range of *P. perna* expanded again in 1990 when two small specimens (2 cm in length) were collected in the western Gulf of Mexico from the Port Aransas Jetty on the east coast of Texas in February 1990 (Hicks & Tunnell 1993). The Texas *P. perna* are now found from the mouth of the Colorado River, Texas south to Veracruz, Mexico (Sea Grant News Media Center Website 1999). The geographical range of *P. viridis* has also expanded. Morton (1987, p. 159) reports "Siddall (1980a) does not consider *P. viridis* to be naturally distributed along the coast of China or Japan and Arakawa . . . believes the species was introduced into Japan sometime around 1967." In 1990 *P. viridis* was first observed in the southern Caribbean Sea at Port Lisas in Trinidad and by 1992 had spread along the entire Trinidad coast of the Gulf of Paria (Agard et al. 1992). In 1993 *P. viridis* appeared on the Venezuelan coast of the Gulf of Paria and by 1995 was discovered in Isla Margarita (Segnini de Bravo et al. 1998). According to Segnini de Bravo et al. (1998), *P. viridis* is driving *P. perna* from its natural beds in La Esmeralda, Guatapanare and El Morro de Chacopata. *Perna viridis* was later discovered in the northern Caribbean in Kingston Harbour, Jamaica in 1998 (D. Buddo and T. Bowes, pers. comm.). *Perna canaliculus* is

*Corresponding author. E-mail: debi@mote.org; Fax: +1-941-388-4312.

*Editor's note: manuscript received January 26, 2001; accepted for publication March 3, 2001.

still geographically isolated, however Carlton (1992) expresses concern that *P. canaliculus* will spread to California where it is now imported daily in large numbers for human consumption. The discovery of introduced populations of *P. perna* and *P. viridis* make the identification of these species based solely on geographic location unworkable.

Since *Perna perna* and *P. viridis* are no longer geographically separated and are difficult to differentiate from each other because of their highly variable morphological characters, other laboratory procedures are necessary to positively identify these species. *Perna viridis* and *P. perna* have been shown to express dimorphism in chromosome numbers and can be distinguished from each other using cytological characters. *Perna viridis* has 15 pairs of homologous chromosomes (Ahmed 1974) and *P. perna* (including introduced Texas populations) has 14 pairs of homologous chromosomes (Ahmed 1974; Jacobi et al. 1990; Holland et al. 1999). Unfortunately, no karyotype analysis is available for *P. canaliculus*. In this report, we confirm the identity of green mussels in Hillsborough Bay as *P. viridis* utilizing both morphometric and cytogenetic characters. We further describe its present well-established distribution throughout and beyond the Tampa Bay estuarine system.

MATERIALS AND METHODS

Initial specimens for identification were collected at the TECO Gannon Station Power Plant in Hillsborough Bay (Fig. 1). Specimens were collected from the screens of the water intake channel by a diver and from inside the intake tunnels during routine maintenance on 15 July 1999. Preserved voucher specimens are deposited in the Division of Invertebrate Zoology, American Museum of Natural History, New York (AMNH 290101), Mote Marine Laboratory (MML 8027.00, 8028.00, 8029.00) and at Lamar University (LU 100399).

Specimens for cytological analyses were collected from the intake boot (flared flange at the base of the water intake pipe) and tunnels of the same power station on 13 October 1999. Chromosome preparations were obtained from gill tissue using a modified colchicine-Giemsa technique (Yaseen 1995; Holland et al. 1999). Specimens were immersed in 0.05% colchicine in aerated 35 ppt seawater at room temperature for 12 h. After this, gill tissues were isolated and placed into a hypotonic solution of 0.8% sodium citrate for 40 min. Tissues were fixed twice in freshly prepared mixtures of 3 parts methanol to 1 part glacial acetic acid for 20 min each, then left in the fixative for 12 h. Cell suspensions were prepared by gently grinding tissues with a microtube pestle in a 1.5 ml microcentrifuge tube containing 60% acetic acid. Disaggregated tissues were then transferred back into fresh fixative by pipette. Cell suspensions were then dropped on cleaned glass slides held at a 45 ° angle from a height of 15 cm. Slides were air-dried then stained with a 24:1 mixture of 0.1 M phosphate buffer (pH 6.8) and Giemsa for 5 min. Photographs were taken of representative mitotic spreads and karyotypes were formed.

Florida Fish and Wildlife Conservation Commission (Florida

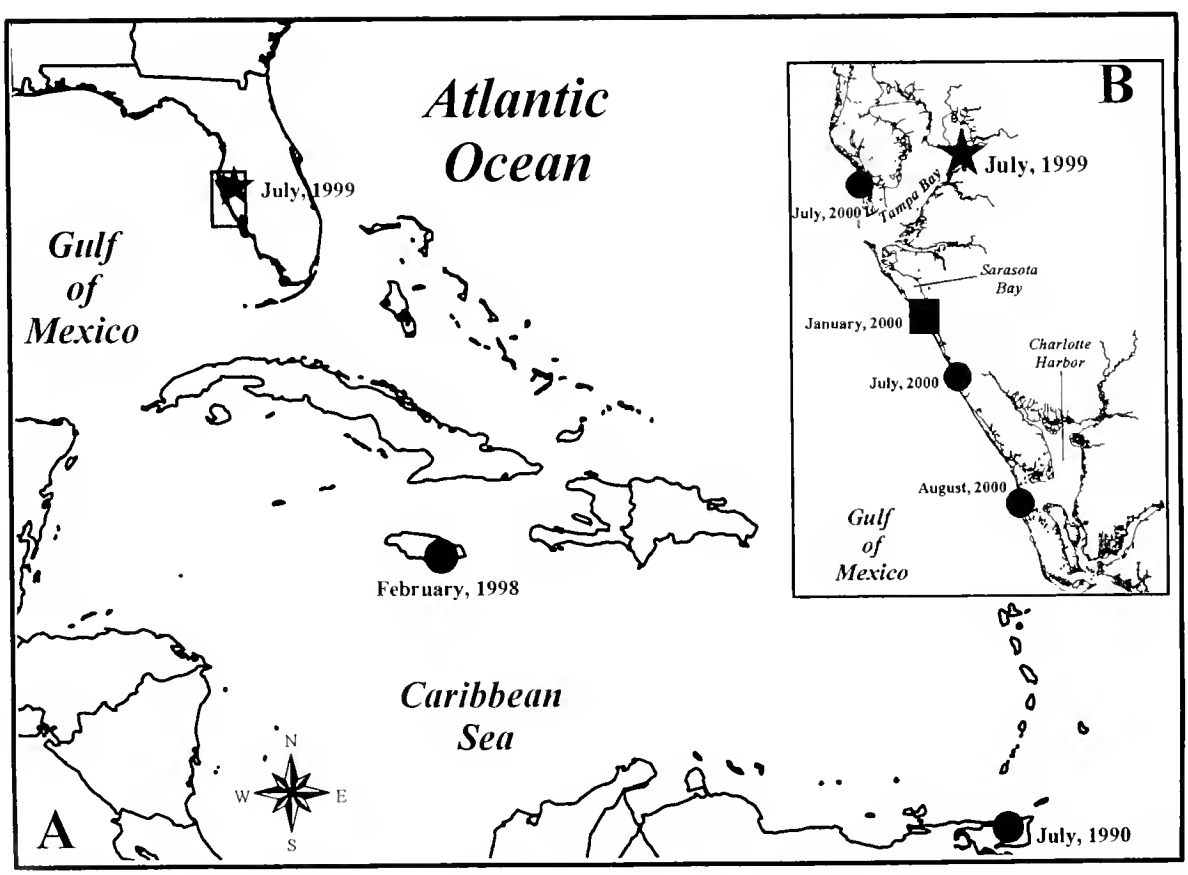

Figure 1. (A) Confirmed sightings of *Perna viridis* in the Caribbean Sea and Gulf of Mexico. (B) Selected documented sightings of *Perna viridis* along the central west coast of Florida.

Marine Research Institute, St. Petersburg, Florida), Mote Marine Laboratory (Sarasota, Florida), U. S. Coast Guard Cutter *Joshua Appleby* (based in St. Petersburg, Florida), Florida Caribbean Science Center (U. S. Geological Survey, Gainesville, Florida), and Great Lakes Science Center (U. S. Geological Survey, Ann Arbor, Michigan) conducted several surface and diving surveys to determine the extent of the introduction of *P. viridis* along the western coast of Florida.

RESULTS

Morphological characters of 26 mature specimens ranging from 24–87 mm in shell length were examined. All specimens have a two-part retractor muscle scar and no anterior adductor muscle scar that is consistent with mussels belonging to the genus *Perna* (mussels belonging to the genus *Mytilus* have a single retractor muscle and an anterior retractor muscle) (Siddall 1980a; Vakily 1989). The specimens were predominantly brilliant green and blue-green sometimes having concentric blue-green bands and the central portion of the shell light brown in some specimens, matching descriptions for *P. viridis* according to Siddall (1980a,b), Vakily (1989), and Dance (1974). Adult shell shape and muscle scars (Fig. 2) corresponded closely to *P. viridis*, as depicted in Siddall's (1980a) comparative review. The mantle margin of preserved and living specimens showed no enlarged sensory papillae, which are characteristic of *P. perna* (Siddall 1980a). Morphological observations of the 26 specimens suggested identification as *P. viridis* but did not conclusively exclude *P. perna*, known to occur along the nearby Gulf coast of Texas.

A diploid number of 2n = 30, characteristic of *Perna viridis*, was scored in 18 mitotic metaphases from two individuals. Qualitative morphological groupings of chromosomes indicated 10 meta-submetacentric and 5 subtelocentric pairs (Fig. 3), consistent with the chromosome morphology for *P. viridis* presented by Ahmed (1974). These results confirmed the tentative morphological identification as *P. viridis*, and indicate the introduction of a second alien pernid mussel to the Gulf of Mexico.

Since its initial discovery at TECO Gannon Station Power Plant in Hillsborough Bay, TECO has reported the presence of *P. viridis* at their Big Bend Station Power Plant in Lower Hillsborough Bay since July 1999 (E. Bietia, pers. comm.); and Florida Power Corporation, Bartow Power Plant on Weedon Island near the entrance to Old Tampa Bay, Florida (27°51′40″N; 82°36′09″W) first noticed these mussels in July 1999 (D. Bruzek, pers. comm.). Range surveys have found living *P. viridis* specimens as far north as John's Pass in St. Petersburg, Pinellas County, Florida, as far south as the Venice Fishing Pier (Venice, Sarasota County, Florida) in the Gulf of Mexico (M.A. Blouin, A. J. Benson, pers. comm.). The largest specimens (many exceeding 100 mm) have been found in Tampa Bay. Specimens found outside of Tampa Bay have been relatively small (1–40 mm). Well-established communities of *P. viridis* have been found in Hillsborough Bay, Old Tampa Bay, Middle Tampa Bay, Lower Tampa Bay, Boca Ciega Bay, and Lower Manatee River (D.C. Marelli, A.J. Benson, M.A. Blouin, C. O'Neil, pers. comm.). The first specimen (10 mm) discovered in Sarasota Bay was found on an invertebrate collecting box in New Pass in January 2000. Four out of eight specimens collected from the Mote Marine Laboratory's New Pass intake pump (19 April 2000) were completely brown (including the inside lip). Over 800 specimens of *P. viridis*, sizes ranging from 0.6–10 mm, were inadvertently collected on a PVC tidal gauge that had been attached to the Apollo Beach Pier for 41 days (29 April to 8 June 2000). Juvenile specimens collected off this tidal gauge which ranged in size from 0.6 to approximately 2.5 mm were golden colored with concentric reddish-brown zigzag markings; specimens greater than 2.5 mm started to develop a green lip; specimens greater than 3 mm showed alternating concentric green banding with the reddish-brown zigzag markings; specimens greater than 4.5 mm started developing their green lip with no banding. Several completely brown juveniles were found.

DISCUSSION

Carlton's 1992 review of introduced marine and estuarine mollusks of the Atlantic, Gulf and Pacific coasts of North America revealed that 36 introduced species have become established. *Perna perna* was the only clearly introduced marine mollusk in the Gulf of Mexico (Carlton 1992). Turgeon et al. (1998) states there are now 47 introduced species of marine and estuarine mollusks in North America: 25 bivalves and 22 gastropods. *Perna viridis* now

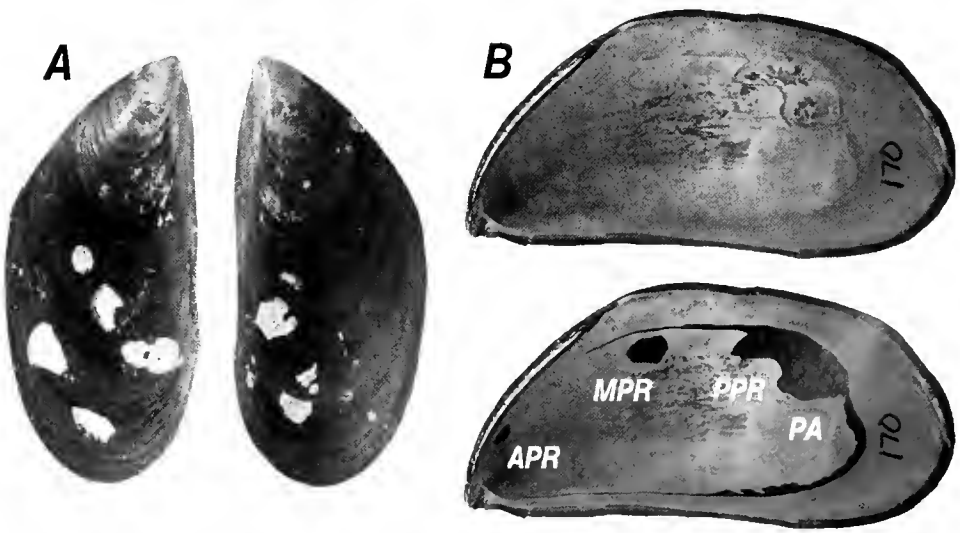

Figure 2. Shell morphology of *Perna viridis* from Tampa Bay, Florida. (A) External view, shell length 87 mm. (B) Internal view of right valve, shell length 104 mm; lower view with enhanced muscle scars and pallial line. APR, anterior pedal retractor muscle; MPR, middle pedal retractor muscle; PPR, posterior pedal retractor muscle; PA, posterior adductor muscle.

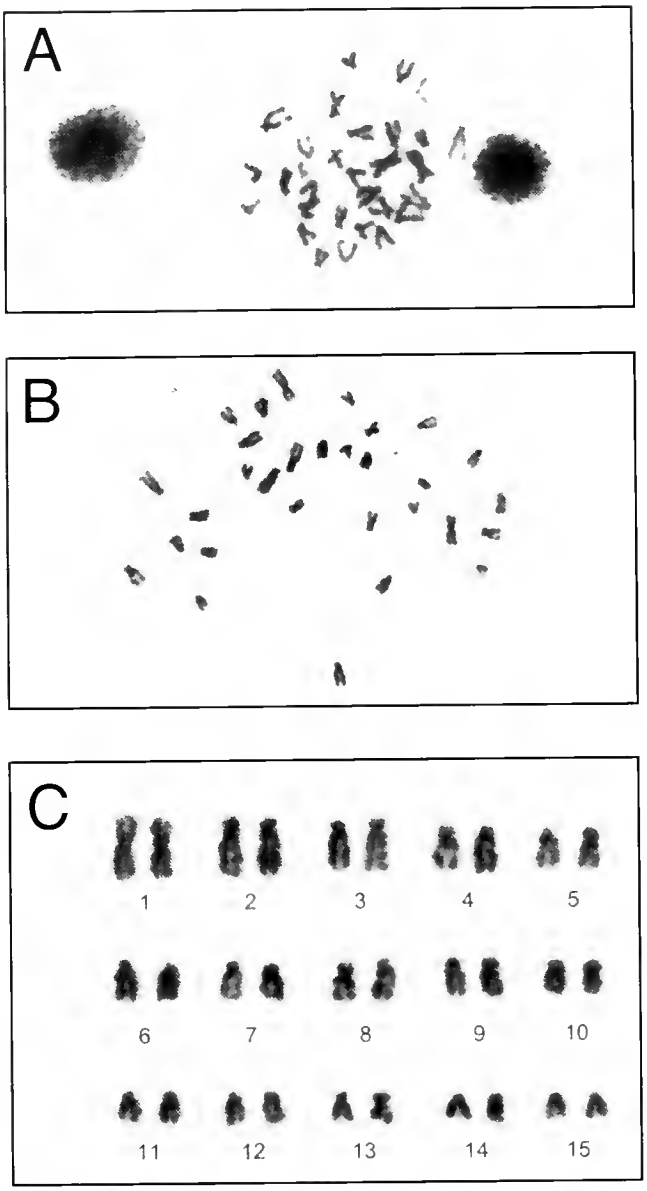

Figure 3. Mitotic chromosomes (A and B) and standard karyotype (C) (from B) prepared from gill tissue from *Perna viridis* specimens collected October 13, 1999 from TECO's Gannon Power Station, Hillsborough Bay (in Tampa Bay), Florida. The 15 pairs of chromosomes are diagnostic for *P. viridis*.

joins these lists as the second introduced mollusk in the Gulf of Mexico and warrants concern as a potential ecological threat to coastal waters of North America (Morton 1997).

Perna viridis shares many characters common to other invasive bivalve species (Morton 1997). For example: *P. viridis* has an extensive capacity for larval and adult dispersal, early maturity, rapid growth rate, and high productivity. *Perna viridis* has also been very successful at finding suitable habitat along the southeastern coast of the Gulf of Mexico.

Extensive Capacity for Dispersal

The planktotrophic larval stages of *Perna viridis* remain free-swimming for 10–20 days (Siddall 1980b, Vakily 1989), during which they can be dispersed over great distances by ocean currents or in the ballast water of ocean-going ships (Carlton 1992). *Perna* species also foul the hulls and anchor chains of transoceanic vessels as byssally-attached adults by which they can be transported internationally (Carlton 1987). Both of these mechanisms were apparent factors in the 1986 introduction and subsequent extraordinarily rapid dispersal of the freshwater zebra mussels (*Dressenia polymorpha*) through the inland waters of North America (Keevin et al. 1992, Claudi & Mackie 1994). Barge and other commercial shipping traffic plying marine/estuarine Intracoastal Waterway (ICWW) interconnecting the Gulf of Mexico and Atlantic states (from the southeastern tip of Texas to Boston, Massachusetts) provide an accessible mechanism for dispersal of *Perna viridis* beyond its present southeastern Gulf of Mexico range.

Early Maturity

Perna viridis becomes sexually mature at 15–30 mm shell length — approximately 2–3 months after fertilization (references in Siddall 1980b; Vakily 1989). In stable tropical environments, spawning can occur year round exhibiting two more-or-less prominent peaks (Vakily 1989; Siddall 1980b; Huang 1985). Spawning can also be easily induced by rapid changes in water temperature (Vakily 1989; Siddall 1980b). Larvae settle within 15-20 days if a suitable substratum (i.e. some type of hard surface — natural or man-made) is present.

Rapid Growth

The combined effects of a number of environmental factors such as water temperature, salinity, currents, food availability, densities and pollution have a considerable effect on the growth rates of *P. viridis* (see Vakily 1989). Morton (1987, p. 163) stated, "Throughout its broad range, *P. viridis* has been reported to have a phenomenal growth rate of some 10 mm per month . . ." Vakily (1989) examined previously published data and compiled growth rates for wild cultures of *P. viridis* ranging from 2.2–10.6 mm per month. Huang et al. (1983) projected an annual growth rate of 60 mm in the relatively polluted waters of Tolo Harbour, Hong Kong. A rough estimate of growth rate of Florida specimens was calculated using the largest specimen (10 mm) collected from the PVC tide gauge at Apollo Beach Pier using shell length/number of days substratum was submerged. This calculation assumes *P. viridis* larvae settled almost immediately, the largest specimen collected was the first to settle, no predation, and a constant growth rate. The estimated growth rate for this specimen was 7.2 mm per month. The following age approximations are based on this growth rate. The specimens collected initially from the TECO Gannon Station Power Plant (15 July 1999) ranged from 24.4–86.6 mm in length, and are estimated to be 3–12 months old, suggesting that initial settlement occurred in July 1998. Some of the largest specimens (over 100 mm) were collected from shipping channel marker buoys in Middle Tampa Bay (14 December 1999); the largest specimen (109.8 mm) is estimated to be over 15 months old suggesting initial settlement occurred in September 1998. The specimens collected on the PVC tide gauge at Apollo Beach (8 June 2000) range in size from 0.6–10 mm and are estimated to be 2–41 days old.

There is considerable fluctuation in growth rates and population densities of all species of *Perna* caused by the combined effects of several environmental factors such as water temperature, food availability [especially chl-a and particulate organic carbon (Rivonkar et al. 1993)], setting densities, currents exposure, and

pollution (Vakily 1989). The highest densities of *P. viridis* in Hong Kong are consistently recorded from Tolo Harbour (4000 adult individuals m^{-2}) and Victoria Harbour (200–246 adult individuals m^{-2}) which are polluted by domestic, agricultural and industrial effluents (Huang et al. 1983). The lowest densities in Hong Kong waters (<100 m^{-2}) are recorded from eastern (exposure to strong wave action), southern (exposure to strong wave action) and western waters (salinities consistently <5 ppt) (Morton 1987). Huang et al. (1983) reported the highest density recorded from Tolo Harbour was 35,000 m^{-2}.

When living in a favorable area, *P. viridis* has been found to spawn year round (reference in Huang et al. 1983). Cheung (1993) studied *P. viridis* population dynamics in the polluted Tolo Harbour, Hong Kong and states (p. 20) "With high densities and a fast growth rate, the productivity of the mussel bed is considerable and is higher than many bivalve populations." Hicks and Tunnell (1995) reported that the closely related *P. perna* could be found forming a distinct mussel belt on the lower mid-intertidal zone of granite jetties in densities of up to 27,200 m^{-2} small individuals (mean = 16 mm). These jetties commonly support 10,000–12,000 individuals m^{-2} (Hicks and Tunnell 1995). Hicks and Tunnell have found on average 25,000–30,000 individuals m^{-2} of *P. perna* spat; the maximum density found was 127,000 m^{-2} (Sea Grant Media News Center website 1999).

Habitat

Tampa Bay provides hard substrata and temperature/salinity regimes similar to those where *P. viridis* naturally occurs in the Indian and southwestern Pacific Oceans as well as areas such as Japan and Venezuela where *P. viridis* has been introduced. It is a subtropical estuary located on the west central coast of peninsular Florida and is the largest open water estuary in the state (Estevez 1989; Lewis and Estevez 1988). It is a Y-shaped embayment, 56 km in length and 16 km wide encompassing over 1000 km^2 (Estevez 1989; Pribble 1999). The average depth of the bay is approximately 4 m. The deepest natural area of Tampa Bay (27 m) is near the mouth of the bay (Pribble 1999). Tampa Bay is also a highly urbanized area and supports many shipping and recreational boating activities. The Port of Tampa is Florida's largest port and consistently ranks among the top 10 ports nationwide in shipping tonnage (Tampa Bay Estuary Program 2000; Meineke 1999). Over 25 million tons of phosphate and related products move through the Port of Tampa annually — more than any other port in the world (Tampa Bay Port Authority 2000). Ships dumped an estimated 543 million gallons of ballast water into Tampa Bay in 1996 (Pittman 1999) from around the world, thus providing an excellent transport mechanism for *P. viridis*.

Perna viridis has been able to maintain dense populations in Tampa Bay and is spreading along the southeastern Gulf of Mexico shore and estuaries despite the lack of continuous, natural, rocky intertidal habitats just as *P. perna* has done on the southwestern Gulf of Mexico shore since its introduction to Texas in 1990. *Perna viridis* can be found attached to hard substrata such as rock faces, wharf piles, among algal holdfasts, and mangrove roots. In deeper waters, where hard substrata are not available, initial attachment may be to sediment grains, shell fragments or other mussels resulting in mussel beds on sandy or muddy bottoms (Agard et al. 1992; Hickman 1991; Jeffs et al. 1999; Berry 1978). Disjunct man-made structures including pier pilings, channel markers, buoys, jetties and bulkheads provide excellent surfaces for *Perna* larvae to settle and grow on. Structures like these are common along the southeastern Gulf of Mexico.

Perna viridis prefer temperatures from 31–32 °C in the summer and 26–28 °C in the winter (Vakily 1989; Agard et al. 1992). Nearly linear growth was evident when temperatures were from 23.6–30.8 °C and cessation of growth occurred when winter temperatures were from 17–18 °C in Tolo Harbour, Hong Kong (Cheung 1993). The low (6 °C) and high (37.5 °C) lethal temperatures for *P. viridis* were recently determined through laboratory experiments (Segnini de Bravo et al. 1998). Water temperatures range from 11–32 °C in subtidal areas of Tampa Bay and vary more widely in intertidal areas (Lewis & Estevez 1988). Maximum water temperatures of 28–30 °C are found from June through August; minimum temperatures of 15–18 °C occur from December through February (Pribble 1999).

Perna viridis prefers salinities 27–33 ppt although laboratory tests showed 50% survival rate after two weeks of exposure to 24 and 80 ppt (reference in Vakily 1989; Agard et al 1992). The low (0 ppt) and high (64 ppt) lethal salinities for *P. viridis* were recently determined through laboratory experiments (Segnini de Bravo et al. 1998). *Perna viridis* can also survive extended exposures to salinities as low as 20 ppt that can occur after a heavy rain (Agard et al. 1992). As would be expected, salinity varies throughout Tampa Bay — higher salinities are found near the mouth of the bay in areas that interact strongly with the Gulf of Mexico; lower salinities are found in areas affected by the inflow of fresh water from rivers and occur in regions farthest away from the Gulf of Mexico (Pribble 1999). Maximum salinities, up to 38 ppt usually occur in June (Pribble 1999). Lowest salinities, down to 15 ppt usually occur in September (Pribble 1999). The rapid dispersal of *P. viridis*, its high thermohaline tolerance and establishment of successful colonies in the southern Caribbean Sea and Tampa Bay suggest that it will continue to spread in the Gulf of Mexico.

SUMMARY

Rayl (1999, p. 6) states: "Experts estimate that aquatic invasive species cost the United States at least $2 billion every year, including fisheries losses, removal and recovery efforts, and sport fishing losses — and the figure is projected to rise." Considering the reproductive rate, growth rate of *Perna viridis* and the similarity in environmental conditions between the southwestern coast of Florida and this mussel's natural habitats, area scientists, resource managers, and others are concerned about its potential impact to native communities as well as coastal economics. Introduced aquatic species frequently cause massive transformation of the structure and function of native ecosystems. Like other introduced species, *P. viridis* has the biotic potential to flourish and to out-compete native species. Economically, the presence of dense mussel colonies on water intake systems, channel markers and buoys, threatens to increase the frequency of maintenance activities and their associated costs. The capacity of *P. viridis* to attach byssally to hard surfaces makes it a major macrofouling threat to industrial facilities drawing raw seawater for operations (Rajagopal et al. 1995). *Perna viridis* is already creating serious operational problems for many power plants and other water intake systems around the world such as Madras Atomic Power Station in southern India (Rajagopal et al. 1991) and Jamaica Private Power Company (T. Bowes, pers. comm.). Byssal mats that are formed by dense population of *P. viridis* are already a problem for local power plants. These byssal mats (and all that grows in them) are

ripped off the hard substratum by the water current flowing to the condensers. The inflowing water pushes the mats against the small pipes in the end of the condensers and the mats act like a clogged air-conditioning filter. This causes pumps to work harder, overheat and potentially cause plant shut down (E. Beitia and D. Bruzek, pers. comm.). In April 2000, *P. viridis* was found growing inside one of the water intake pumps at Mote Marine Laboratory and caused the pump to overheat requiring the pump to be shut down decreasing the amount of water available for daily operations (C. Traxler, pers. comm.). Heavy colonies could also potentially sink channel marker buoys, creating a hazard to navigation as was seen in Texas with *P. perna* (Hicks pers. comm.).

All of the news may not be bad. All three *Perna* species are a valuable food source high in protein and are harvested from wild population or aquaculture facilities for human consumption (Vakily 1989). In 1955 the first commercial mussel farm started in the Philippines (Vakily 1989). Thailand (*P. viridis*) and New Zealand (*P. canaliculus*) are the only two other countries where *Perna* is being cultured on an intensive commercial scale (references in Vakily 1989). India (*P. viridis*) is the only country in Asia with a substantial mussel industry not based on culture; over 3,000 tonnes are harvested annually (Vakily 1989). Rafts, racks, bamboo poles, date-palm stakes, iron bars, ropes, rope-webs and longlines are used to culture *Perna* (Vakily 1989). Mussel seed are rarely produced artificially but are collected on spat collectors during peak spawning seasons (Vakily 1989). Aquaculture of *P. canaliculus* started about 20 years ago and has continued to expand, with production almost doubling in the last 4 years to reach 70,000 tonnes y^{-1} (Jeffs et al. 1999). *Perna canaliculus*, marketed as Greenshell™ mussel, is internationally recognized as a premium-eating mussel and is thought to possess unique remedial properties in rheumatoid and osteoarthritis (references in Jeffs et al. 1999). The success of *P. viridis* in the southeastern Gulf of Mexico, the demand for these mussels in the food industry and potential biomedical importance could spawn new aquaculture opportunities.

In rapid response to the discovery of *Perna viridis* in Tampa Bay, staff at the Florida Fish and Wildlife Conservation Commission (at the Florida Marine Research Institute, St. Petersburg) and Mote Marine Laboratory (Sarasota) have issued public announcements in the printed and audio media, as well as on the World Wide Web (http://www.mote.org~debi/perna.phtml, http://www.fmri.usf.edu/invert/pviridis.htm) to inform the public and solicit information about the spread of the mussel (Associated Press, 1999; Pittman, 1999; Roberts, 1999; Florida Fish and Wildlife Conservation Commission, 2000). Meeting presentations and posters have been given (Ingrao et al. 1999; Benson et al. 1999; Ingrao et al. 2000) and live-animal displays and requests for further information were put in place at the publicly available Mote Marine Aquarium. In spite of the activity surrounding this newly recorded introduction, the mussel is already well established in its new environment and its eradication is not expected. Clearly, priorities must be directed at monitoring its ecological and economic impacts, and at developing methods for its control and use.

ACKNOWLEDGMENTS

Special thanks are due to C. Barringer and E. Beitia of Tampa Electric Company for reporting the initial sighting and sending specimens to Mote Marine Laboratory. We also thank E. Estevez and J. Culter (MML) for reviewing the manuscript. The authors would like to thank the following for sharing *Perna viridis* sighting and size information: A. Benson (Florida Caribbean Science Center, U. S. Geological Survey, Gainesville, Florida), M. Blouin (Great Lakes Science Center, U. S. Geological Survey, Ann Arbor, Michigan), T. Bowes (Jamaica Private Power Plant), D. Bruzek (Florida Power Corporation, Paul L. Bartow Power Plant), D. Buddo (University of the West Indies, Jamaica), D. Marelli [Florida Fish and Wildlife Conservation Commission (at the Florida Marine Research Institute, St. Petersburg, Florida)], and C. O'Neil (U. S. Coast Guard Cutter *Joshua Appleby*, St. Petersburg, Florida).

Special thanks to the following MML staff, volunteers and interns for their assistance with data entry and image preparation, literature searches, laboratory and field work: S. Arbuckle, Andrea Baird, K. Churchill, J. Goldstein, D. Harayda, W. Hoebel, S. Howard, K. Ingrao, N. Jacobs, N. Levin, R. Marzek, J. Massoud, M. Oliver, J Osterhoudt, T. Pancake, J. Perry, J. Sadler, L. Stevenson, S. Stover, C. Traxler, J. Van Horn, and V. Zoll. Figure 2 was prepared by S. Thurston (AMNH). David Hicks wishes to thank M. Haiduk for use of his laboratory at Lamar University in preparing karyotypes.

ESTABLISHMENT OF THE GREEN MUSSEL, *PERNA VIRIDIS* (LINNAEUS 1758) (MOLLUSCA: MYTILIDAE) ON THE WEST COAST OF FLORIDA[†]

AMY J. BENSON,[1,*] DAN C. MARELLI,[2] MARC E. FRISCHER,[3] JEAN M. DANFORTH,[3] AND JAMES D. WILLIAMS[1]

[1]*U.S. Geological Survey, Florida Caribbean Science Center, 7920 NW 71st Street, Gainesville, Florida 32653;* [2]*Academic Diving Program, Florida State University, 036 Montgomery, Tallahassee, Florida 32306-2310;* [3]*Skidway Institute of Oceanography, 10 Ocean Science Circle, Savannah, Georgia 31411*

ABSTRACT In 1999, the green mussel, *Perna viridis*, was first observed in Tampa Bay, Florida. This was the first reported occurrence of this Indo-Pacific marine bivalve in North America. The mussels found in Tampa Bay were confirmed to be *P. viridis* based on both morphological and genetic characteristics. Since the initial discovery, surveys in Tampa Bay and on the west coast of Florida have documented the growth, recruitment, and range expansion of *P. viridis*. From November 1999 to July 2000, the mean shell length of a Tampa Bay population increased from 49.0 mm to 94.1 mm, an increase of 97%. Populations of *P. viridis* are successfully reproducing in Tampa Bay. Recruitment was observed on sampling plates in May and continued through July 2000. The full extent of mussel colonization is not clear, but mussels were found outside Tampa Bay in St. Petersburg, Florida, south to Venice. Based on these studies it is evident that *P. viridis* has successfully invaded Tampa Bay and the west coast of Florida. The long-term impact of *P. viridis* on native communities off the west coast of Florida cannot be predicted at this time.

KEY WORDS: *Perna viridis*, introductions, green mussel, Florida, Gulf of Mexico

INTRODUCTION

Florida's ecosystems have been and continue to be the recipients of many new nonindigenous species introductions and invasions (U.S. Congress 1993, Carlton & Ruckelshaus 1997). Tampa Bay, located on the west coast of central Florida, has been particularly open to exotic species introductions because of its temperate to subtropical climate and active industrial, commercial, and recreational use. In August of 1999, the Tampa Electric Company reported finding an unknown bivalve fouling the surfaces in their cooling water intake tunnels at both their Gannon and Big Bend power stations in and near the city of Tampa, Florida (G. Shofner, personal communication). They were identified as *Perna viridis* (Linnaeus 1758) based on their karyotype (Ingrao et al. 2001). This was the first report of this species in North America. Nonindigenous species are potentially invasive when they display some of the following characteristics: high fecundity, short generation time, long-lived, high dispersal rate, phenotypic plasticity, broad native range, abundant in native range, and tolerant of a wide range of conditions (Williams & Meffe 1998).

Perna viridis is native to the coastal marine waters of the Indo-Pacific region including the Persian Gulf to the South China Sea (Siddall 1980, Vakily 1989). It is a byssally attached, sessile bivalve naturally inhabiting estuarine waters where the salinity ranges from 27-33 PSU, although it tolerates salinities as low as 16 PSU (Sundaram & Shafee 1989). The optimal annual temperature range for *P. viridis* is 26–32°C; survival rate was 50% at 10° and 35°C after two weeks of exposure (Sivalingam 1977). *Perna viridis* exhibits a wide tolerance for sub-optimal environmental conditions, tolerating large fluctuations in sediment flux and organic enrichment (Morton 1985, Lee 1986). Like other marine mussels, *P. viridis* attaches to hard substrates, but is also capable of colonizing soft substrates (Agard et al. 1992). *Perna viridis* generally occur at depths from the surface to 10 m, although settlement of juvenile mussels has been reported greatest at depths of between 2 and 3 meters (Tan 1975, Cheong and Chen 1980). This species is a suspension feeder selectively feeding primarily on algae (Sivalingam 1977, Yap et al. 1979). It has been intensively cultured within its native range as a protein source for human consumption and been shipped to many islands in the South Pacific over the last several decades for this purpose (Chalermwat et al. 1988, Eldredge 1994).

Perna viridis is a dioecious broadcast spawner (Sivalingam 1977) displaying a wide variation in spawning pattern within its native range, encompassing unimodal, bimodal, and asynchronous modes (Walter 1982, Lee 1986, Tuaychareon 1991, Rajagopal et al. 1998b). Following fertilization, zygotes develop into free-swimming veligers within 16 hours, and umbonate larvae develop at about 20 hours post fertilization (Sivalingam 1977). Larvae remain free-swimming for 2–3 weeks, then settle onto hard substrata and byssally attach (Vakily 1989, Tuaychareon 1991).

There are currently three species of *Perna* (*P. perna* (Linnaeus 1758), *P. canaliculus* (Gmelin 1791), and *P. viridis*). They inhabit tropical and subtropical coastal marine waters worldwide; however, none occur naturally in North America (Siddall 1980). Within the past decade, both *Perna perna* (Hicks & Tunnel 1993) and *Perna viridis* (Ingrao et al. 2001) have been introduced into the Gulf of Mexico and southern Caribbean (Agard et al. 1992, Rylander et al. 1996, D. Buddo, personal communication). The known distribution of *Perna viridis* in the western hemisphere includes the following countries: Venezuela, Trinidad, Jamaica, and peninsular Florida in the United States (Fig. 1). While *P. perna*, the edible brown mussel, is native to the southern Caribbean, *P. viridis* is not, and until the recent introductions of *P. perna* and *P. viridis* into the Gulf of Mexico and southern Caribbean the species did not occur sympatrically (Siddall 1980). *Perna canaliculus*, known as the greenshell mussel, is native to waters surrounding New Zealand. Shell color, morphology, and especially geographic location have been used in the past to identify and distinguish among the species of *Perna* (Siddall 1980). Although color has been used as a distinguishing characteristic, it is not a definitive feature. Shells of young *P. viridis* mussels are a brilliant green while the adults are dark green to brown, and young *P. perna*

Figure 1. Shaded circles represent *P. viridis* populations along coastlines.

observed in Texas can be green but are brown as adults (D. Hicks, personal communication). *Perna viridis* can be distinguished from *P. perna* by examining the karyotype of somatic cells: *P. perna* has 28 chromosomes while *P. canaliculus* and *P. viridis* have 30 (Ahmed 1974, Holland et al. 1999, Ingrao et al. 2001). Therefore, because color and morphological characters are unreliable for distinguishing between the species in this genus (Siddall 1980), more defining characteristics are needed to determine the identity among species of the genus *Perna*.

METHODS

Study Sites

From November 17–19, 1999, biologists from the U.S. Geological Survey (USGS) and the Florida Marine Research Institute (FMRI) sampled bridge pilings, buoys, channel markers and shorelines of Tampa Bay. The northern section of the Bay consists of two smaller bays, Hillsborough and Old Tampa bays. Because the two power plants that had reported finding *Perna viridis* were located in Hillsborough Bay, we decided to sample Old Tampa Bay to determine the species' range within the entire Tampa Bay system. Green mussels were collected by hand off bridge pilings from just above the water surface to approximately one-half meter below the surface. In addition, we qualitatively surveyed two bridges in Old Tampa Bay using scuba divers in late February 2000. Divers also attempted to locate additional populations of mussels near the mouth of Tampa Bay from March through July 2000. In the latter part of July, we expanded our survey along the west coast of Florida to further document the extent of their range. We began surveying coastal waters south of Tampa Bay at Venice and proceeded in a northerly direction to Johns Pass at the north end of Treasure Island. In addition to direct observation, we received reports of *P. viridis* observations from private citizens, governmental agencies and other organizations, which were helpful in locating other populations.

Approximately thirty adult *P. viridis* were collected from the wooden fenders beneath the Howard Frankland Bridge (Interstate 275) over Old Tampa Bay during late February 2000 and monthly thereafter. Mussels were fixed in 5% seawater formalin and preserved in 70% ethanol for future analysis of reproductive condition. These mussels were examined morphologically and used to determine the mean length of adults in the Old Tampa Bay population. In addition, we established recruitment collectors in the same vicinity. Recruitment collectors consisted of three 15 cm × 15 cm unglazed quarry tiles attached to a stainless steel frame which were protected from predation by a section of 1 cm × 1 cm polypropylene mesh. Tiles were replaced monthly and exposed tiles were taken to the laboratory for examination using a magnifier lamp as well as a dissecting microscope. All *P. viridis* recruits settling on the tile surface were counted in the laboratory. Scrapings from pier and bridge pilings were also examined in the laboratory to determine the identity of any commensal organisms.

Identification by Genetic Characterization

Isolation of Total DNA from Bivalves

DNA was purified from specimens of *P. perna* (Port Mansfield, Texas), *P. viridis* (Pelican Island, Trinidad), *P. canaliculus* (Marlborough Sound and Castlepoint, New Zealand), and *Perna* species collected from Tampa Bay, Florida. Whole animals were collected, preserved in 95% ethanol or isopropyl alcohol, and shipped by express mail to the laboratory. Total DNA was purified from adductor muscle tissue (*ca.* 0.5–0.14 g) as previously described (Frischer et al. 2000b). This protocol routinely yielded from 30 to 800 µg DNA/g tissue of high molecular weight genomic DNA suitable for PCR amplification depending on the source of tissue.

PCR Amplification of the Mitochondrial Cytochrome C Oxidase Subunit I Gene

A 713-bp fragment of the mitochondrial cytochrome c oxidase subunit I gene (COI) was amplified using primers LCO1490 (5′- ggt caa caa atc ata aag ata ttg t) and HCO2198 (5′- taa act tca ggg tga cca aaa aat ca) from each of the mussel species (Baldwin et al. 1996). Primers were synthesized using an ABI DNA/RNA synthesizer (model 394) by the Molecular Genetics Facility at the University of Georgia. Amplification was accomplished using the Qiagen *Taq* PCR Master Mix System following the standard protocol recommended by the vendor (Qiagen, Valencia, Calif.) except that to each 25 µl reaction, 0.05 µl of T4 Gene Protein (Roche Molecular Biochemicals, Indianapolis, IN) was added to enhance amplification. Amplification conditions were as described by Baldwin et al. (1996); 35 amplification cycles (95°C, 1 min; 54°C, 1 min; 72°C, 1 min) initiated by a 3-min denaturation step at 95°C and followed by a 10-min extension step at 72°C.

Sequencing

To facilitate sequencing of the PCR amplified COI gene fragment from the Tampa Bay *Perna* specimen, *P. perna*, and *P. viridis*, and *P. canaliculus* specimens, the COI PCR product was cloned into the bacterial plasmid sequencing vector PCR 2.1 TOPO cloning vector using the TOPO™ TA cloning system following the instructions provided by the manufacturer (Invitrogen, Carlsbad, Calif.). Sequences were determined by automated sequencing at the Molecular Genetics Facility (University of Georgia) using an ABI automated sequencer (models 373 and 377) as previously described (Frischer et al. 2000b). The complete COI amplicon sequence was obtained using the plasmid vector targeted (M13) sequencing primers M13-20-F (5′- tgt aaa acg acg gcc agt) and M13-48R (5′- agc gga taa caa ttt cac aca gga). Complete sequences were assembled using the assembly and editing features of the DNAsis software package version 7.00 (Hitachi Software Engineering Co.).

Phylogenetic Analysis

Sequences were aligned relative to each other and several other COI fragments from other mollusks available in GenBank using the CLUSTAL W version 1.7 multiple sequence alignment algorithm (Thompson et al. 1994). Alignments were viewed and edited using the Genetic Database Editor (GDE) (Smith et al. 1992). Percent sequence similarity between organisms was determined using the sequence alignment procedure available in the DNAsis software package version 7.00 (Hitachi Software Engineering Co.). Phylogenetic trees were inferred and drawn using the TREECON for Windows software package version 1.3b (Van de Peer & De Wachter 1994, 1997) using the Kimura two-parameter model for inferring evolutionary distance. Bootstrap estimates (100 replicates) of confidence intervals were also made using the algorithms in TREECON.

RESULTS

The identity of the *Perna* species collected in Tampa Bay was confirmed to be the green mussel, *Perna viridis*, based on both morphological and genetic characteristics.

Morphological Characteristics

The presence and location of muscles and muscle scars have previously been reported to be useful identifying characteristics for the genus *Perna* (Siddall 1980). The lack of an anterior adductor muscle confirms that the mussel in Tampa Bay is a species of *Perna*. Furthermore, the position of the anterior component of the posterior retractor muscles appears most similar to that of *P. viridis*. Externally, the most obvious characteristic of the mussels collected in Tampa Bay is that both juveniles and adults are a bright green to dark green color (Fig. 2). Although shell color is a poor identifying characteristic for these bivalves, to our knowledge there have been no reports of *Perna perna* that were green as adults. Due to the ambiguities associated with the identification of *Perna* species based solely on morphological and coloration characteristics, specimens of three *Perna* species were genetically compared with the mussels found in Tampa Bay.

Genetic characteristics

An identically sized 713 bp fragment of the mitochondrial encoded cytochrome c oxidase subunit gene was amplified, cloned, and sequenced from each *Perna* species studied. These sequences have been deposited in GenBank. Accession numbers are AF298850, AF298851, AF308731 and AF298852 for *P. perna* (Texas), *P. viridis* (Trinidad), *P. canaliculus* (New Zealand) and *P. viridis* (Tampa Bay), respectively. Phylogenetic comparison between *Perna* species and *Perna* species collected from Tampa Bay indicated that the Tampa Bay specimens were most closely related to *P. viridis* (Fig. 3). The sequence similarity between *P. perna*, *P. viridis*, *P. canaliculus*, and the Tampa Bay species are shown in Table 1. Sequence similarity between *Perna* species ranged from 78.2% to 99.5% with the highest similarity between the Tampa

Figure 2. The green mussel, *Perna viridis*, collected from Tampa Bay, Florida, November 1999.

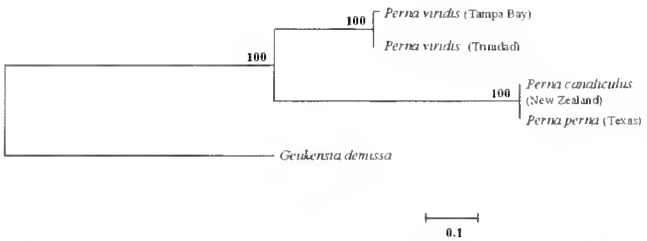

Figure 3. Inferred taxonomic relationship between *P. viridis* in Tampa Bay and other *Perna* species. The phylogenetic tree was derived from nucleotide sequence comparison of a 713 bp fragment of the mitochondrial cytochrome c oxidase subunit I gene (mtCOI). The tree was artificially rooted with the mtCOI sequence from the ribbed mussel (*Geukensia demissa*) retrieved from GenBank (U56844). The scale bar indicates 0.1 fixed nucleotide substitutions per site. Numbers refer to bootstrap values (from 100) for each node.

Bay specimens and the *P. viridis* specimens collected from Trinidad. These results confirm that the *Perna* species currently in Tampa Bay, Florida, is *Perna viridis*.

Distribution, Growth, and Reproduction in Tampa Bay Region

Since the initial discovery of *P. viridis* at two electric power plants in Tampa Bay, Florida, populations have been documented throughout the bay and extending into the Gulf of Mexico. Through July 2000, green mussels have been documented from numerous locations in Tampa Bay (including Hillsborough and Old Tampa bays), Sarasota Bay, and in the Gulf of Mexico from Venice, north to Treasure Island at Johns Pass (Fig. 4). One week after our final survey, mussels were discovered south of Venice at Boca Grande, a barrier island in the Gulf of Mexico just outside of Charlotte Harbor (M. Blouin, personal communication). Mussels were collected at the northernmost and southernmost sites in the final survey; therefore, the full extent of their geographic range along the west coast of Florida is still to be determined.

Mussels collected from the Gannon Power Station (Hillsborough Bay) in October 1999 ranged in shell length from 17.9 to 30.1 mm (mean = 23.6 mm). These animals were reproductively mature and even the smallest individuals began to spawn when they were taken into the laboratory. *Perna viridis* has been reported to achieve sexual maturity in two to three months at a shell length of approximately 20 mm (Vakily 1989, Tnaychareon 1991). The mussels collected in November 1999 from the population of *P. viridis* on the Howard Frankland Bridge (Old Tampa Bay) had a mean shell length of 49.0 mm. Subsequent collections from this population demonstrate rapid growth as the mean length of mussels increased nearly 92% to 94.1 mm in July 2000 (Fig. 5). Growth rates have been reported from a number of areas within the native range. *Perna viridis* in the nutrient rich Hong Kong Harbour grew to a length of 50 mm in the first year, to 75 mm in the second year, and to 85 mm in the third year (Cheung 1993). In a power plant intake structure in India, mussels grew to a length of 27 mm in 49 days and 119 mm in 375 days (Rajagopal et al. 1998a). The highest growth rate recorded is from Singapore at 10.6 mm per month during the first year of culture (Cheong and Chen 1980). According to Vakily (1989), it is difficult to define maximum size and longevity of members of this genus.

Perna viridis recruits were first detected in May 2000 on recruitment collectors placed near the Howard Frankland Bridge in Old Tampa Bay. Small mussels (<10 mm shell length) were prominent on both the collectors and bridge structures during June and July (Fig. 6). Cheung (1993) documented two recruitment periods per year in a Hong Kong harbor, the first from July to September, and the second from November to March.

Tampa Bay community

Tampa Bay is a large estuary approximately 57 km in length and 20 km in width. The entire Tampa Bay watershed encompasses 6,739 km^2 with 967 km^2 of open water. Carlton (1996) views much of the cosmopolitan species that make up the Florida marine biota as cryptogenic. Because it is probable that introductions to Florida by European settlers have occurred for five centuries, it is difficult to differentiate native from exotic species in Florida (Carlton and Ruckelshaus 1997). Commensal organisms, endemic or cryptogenic, found during our surveys to occur with *P. viridis* include other species of bivalves, crustaceans, barnacles, bryozoans, cnidarians, and annelids (Table 2). Though our samples do not represent the entire biota in the bay, we consider them representative of the community in which *Perna viridis* is now established in Tampa Bay.

DISCUSSION

The results of this study indicate that the mitochondrial COI gene can be used to genetically identify *Perna* individuals to the species level. Sequence comparison of amplified mitochondrial COI gene products indicated that the *Perna* species discovered in Tampa Bay, Florida is *Perna viridis*. This confirms the reported presence of *Perna viridis* in the Gulf of Mexico that was based on cytogenetic karotyping (Ingrao et al. 2001). Furthermore, these studies suggest that molecular comparison of the mitochondrial COI gene can provide a diagnostic molecular marker for identifying *Perna* at the species level. However, despite the high similarity between the Tampa Bay and Caribbean *Perna viridis* specimens, five nucleotide differences between the two mussels were observed. The presence of these sequence differences suggests that COI sequences may contain sufficient variation for detecting intrapopulation variation within *Perna viridis* populations. Additional sequencing studies will be needed to test this hypothesis. Further studies will also be required to evaluate whether the COI locus will be useful for larval identification techniques (Frischer et al. 2000b, Bell & Grassle 1998, Baldwin et al. 1996). Interestingly, the similarity between *P. perna* and *P. canaliculus* was extremely high (95.5%) suggesting that these two species may be ecomorphs rather than true species. However, since these results were derived from a single specimen of *P. perna* and seven *P. canaliculus*, additional systematic analysis will be required to confirm this conclusion.

Green mussels were initially identified from Hillsborough Bay in August 1999 at electric power generating stations. However, green mussels were not limited to the vicinity of the power stations and furthermore, larger mussels were found in Old Tampa Bay suggesting that it was the initial colonization site for green mussels in Tampa Bay. Thousands of barnacle-encrusted green mussels were discovered on the bridge pilings there indicating that the mussels had been present for an extended period of time. Although we did not quantify the populations on each bridge piling, it was visually apparent that the number of green mussels on each piling decreased as we sampled from the center of the bridge to the shore. We observed no mussels along the shoreline, which consisted of suitable substrate such as rip-rap, concrete retaining walls, and mangrove prop roots. Most of the mussels were observed subtidally during our surveys of the bridge pilings. However, a smaller

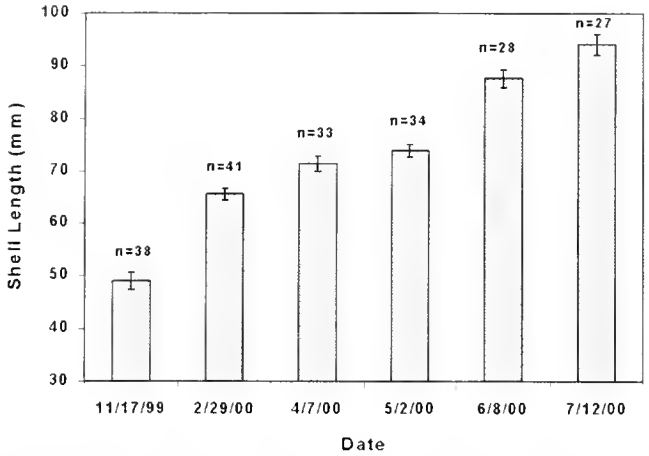

Figure 5. Mean shell length of *Perna viridis* individuals collected from Old Tampa Bay, 1999-2000. Data include means plus and minus one standard error.

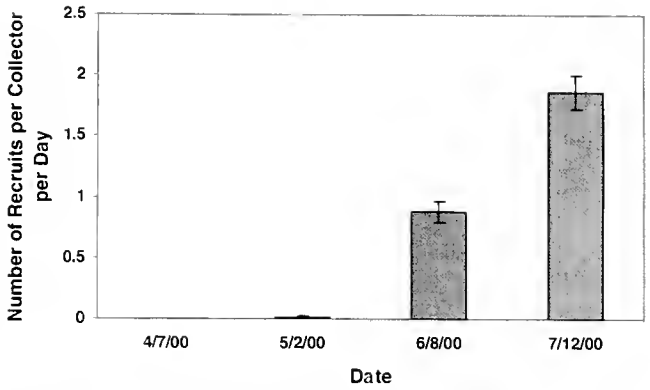

Figure 6. Mean recruitment of *Perna viridis* to collector plates in Old Tampa Bay, Florida, 2000. Data include number of recruits per collector per day plus and minus one standard error.

portion were observed intertidally where they were exposed to atmospheric conditions for short periods.

At the sample sites along the Gulf coast from Venice to Treasure Island (Johns Pass), mussels were smaller and fewer when compared to the sites sampled in 1999 from Old Tampa Bay (A. Benson, personal observation). However, mussels were common enough to be detected on bridge and dock pilings and channel markers after just several minutes of diving. Having observed a visible decrease in the number and size of mussels in our surveys outside of Tampa Bay reaffirmed that the Port of Tampa was the initial site of this introduction from which they subsequently were transported by currents out of the Bay along the coast. We did not observe green mussels in slow-moving backwater areas in the Tampa Bay estuary or along the Gulf coast and Intracoastal Waterway.

Perna viridis is the most recent nonindigenous mollusk to enter Florida, probably introduced into Tampa Bay as larvae entrained in ship ballast water. Ballast water transport has become a major source for the introduction of marine organisms (Carlton and Geller 1993, Carlton and Ruckelshaus 1997). Other modes of introduction such as accidental releases by the seafood or aquaculture industries, or purposeful release of mussels seem far less likely. Although originally from the Indo-Pacific region, we suspect that the source of introduction of green mussels into Tampa Bay was the southern Caribbean region. Just over 40% of the ships arriving in the port of Tampa "in ballast" (carrying significant quantities of water ballast) originate in the Gulf of Mexico or Caribbean, and less than 1% originate in areas even remotely close to the native range of *P. viridis* (Carlton et al. 1995). The spread of *P. viridis* to other areas in Florida and the southeast United States can be expected and will be limited only by the availability of transport vectors and the physiological tolerance of the mussels. Users of industrial water such as power plants may use mechanical or chemical control methods to reduce or eliminate mussels. Efforts to limit future introductions of nonindigenous species must include assessments of risk to native habitats, risk from species or communities in ports of origin, and the risks of potential vectors of introduction (Carlton et al. 1995, Carlton and Ruckelshaus 1997, Simberloff et al. 1997). Concurrently, measures must be developed to prevent such introductions.

Our data and observations demonstrate that *Perna viridis* is able to grow, over-winter, and successfully reproduce in Tampa Bay. In the period since its introduction, estimated to be about two years, the green mussel has colonized mostly man-made habitats throughout the estuary and has entered the Gulf of Mexico where currents have begun transporting larvae south along the Gulf Coast. The rapid growth and maturity, high fecundity, high dispersal rate, and obvious ability for *P. viridis* to thrive in the Tampa Bay estuary indicate that this species is already becoming invasive as defined by Williams and Meffe (1998). As mentioned earlier, *P. viridis* is a tropical species where normal water temperatures range from 26°C to 32°C. Based on water temperatures in Tampa Bay since 1998, green mussels have not yet experienced water temperatures below the LC_{50} of 10°C, but water temperatures have been as low as 12.3°C, much colder than waters in their native range. Historic data as far back as 1974 revealed winter water temperatures were below 10°C only in 1977. If green mussels persist in the Bay, cool temperatures may be selecting for a more cold-tolerant population, increasing the potential for northward expansion. Certainly other water quality parameters may be factors in the establishment of the green mussel elsewhere and deserve further investigation.

We expect *P. viridis* to continue to spread south along the Gulf Coast of Florida, possibly to include the Florida Keys and other Caribbean islands (Fig. 7). Based on surface water temperature data, it is likely that green mussels could survive almost anywhere along the Gulf of Mexico coastline, from Florida to Texas and Mexico. *Perna viridis* may survive in less than optimal water temperatures as far north in the Atlantic Ocean as Charleston, South Carolina. If green mussels were able to survive in suboptimal water temperatures in the United States, occasional below-normal winter air temperatures may lower water temperatures enough to kill or limit populations. We might also expect them to survive along the Hawaiian Islands coasts in the Pacific Ocean and along the coast of Mexico but probably not as far north as California in the United States. We must also be aware of the fact that thermal pollution can provide overwintering refugia in temperate climates such as in Japan, resulting in an even greater distribution in North America.

The biological and economic impacts of *Perna viridis* on the Tampa Bay region are difficult to predict. Areas currently colonized by green mussels are human created substrates and not of

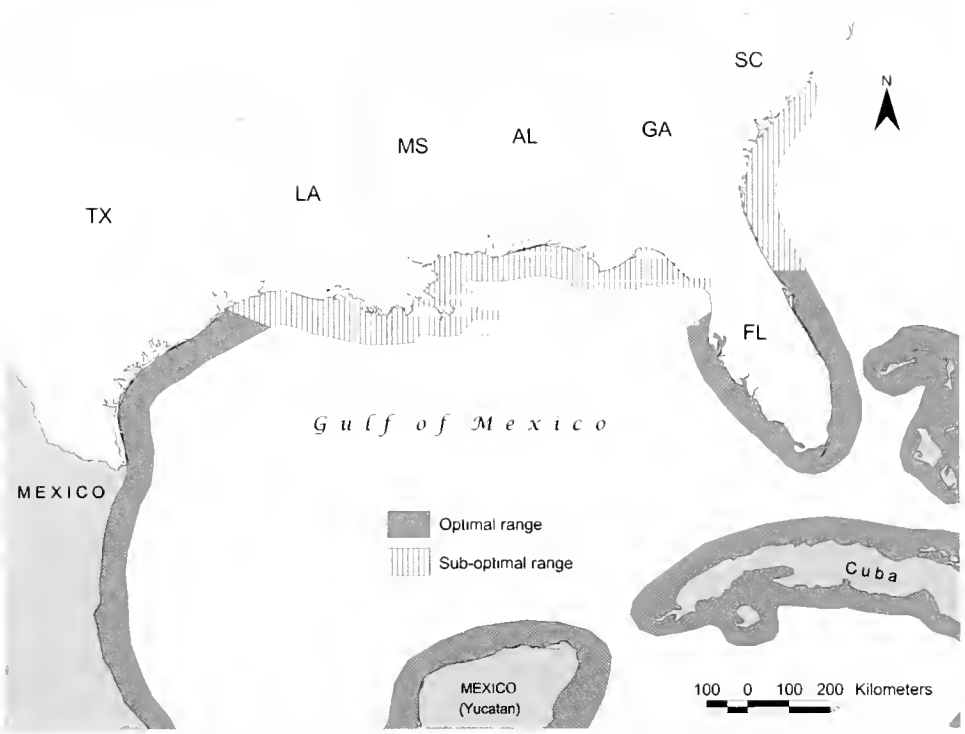

Figure 7. Predicted range of *Perna viridis* in the Gulf of Mexico and western Atlantic waters based on near-surface water temperatures. The lower limit of the sub-optimal range based on LC_{50} of 10°C with two weeks exposure.

particular concern as far as issues of biodiversity are concerned. We are concerned that *P. viridis* will eventually colonize prop roots of the red mangrove, *Rhizophora mangle*, and affect the diversity of the native communities associated with this habitat. Green mussels have already become established on red mangrove prop roots in Trinidad within the past decade (Agard et al. 1992) and more recently in Jamaica (D. Buddo, personal communication). They may also affect the dynamics of the phytoplankton assemblage and increase water clarity in Tampa Bay through active suspension feeding, much as *Potamocorbula amurensis* has in San Francisco Bay and *Dreissena polymorpha* has in numerous freshwater bodies (Alpine and Cloern 1992; Stoermer et al. 1996). However, it is expected that many of the nutrients will be cycled into the benthic community as feces and pseudofeces, possibly causing local shifts in benthic community dynamics (Tsuchiya 1980; Dobson and Mackie 1998, Frischer et al. 2000a).

Impacts are expected to include fouling of unprotected boats and in-water structures such as docks, seawalls, and aids to navigation and interference with cooling water intakes in electric power generating stations. Oddly, green mussels are biofoulers of power plants in their native India (Nair & Murugan 1991; Rajagopal et al. 1995). They are also a major part of the biofouling community in China where they are notorious for fouling navigation buoys with biomasses of as much as 72 kg/m^2 (Yan et al. 1994). *Perna viridis* is also a new member of the biofouling community in Japan. Winter water temperatures normally decimate populations there; however, overwintering of mussels does occur in Tokyo near warmwater discharges (Umemori and Horikoshi 1991). Tampa Bay already has an active fouling community consisting mainly of barnacles, tunicates, and native bivalve mollusks, but none of these animals approaches either the size or the potential accumulated mass of *Perna viridis*. Local electric utilities are already experiencing problems associated with green mussel settlement in intake structures (D. Marelli, personal observation) and it is anticipated that the cost of maintenance in these structures, as well as on navigational buoys and vessels will increase substantially as the *P. viridis* population continues to increase.

ACKNOWLEDGMENTS

We thank Daniel O'Connell of Newcastle University, Newcastle, England and Gary Hill, Robert Lewis, Marc Blouin, and Don Hickey of USGS for collecting samples of green mussels in Florida; Suzanne Dilworth of the Center for Coastal Studies, Corpus Christi, Texas for supplying *Perna perna* samples; Dr. Peter Smith of the National Institute of Water & Atmospheric Research Ltd (NIWA) Wellington, New Zealand for *Perna canaliculus* samples; and Paul Gabbadon and Addison Titus of the Institute of Marine Affairs, Trinidad for *Perna viridis* samples. We also thank Jon Fajans of the University of Florida for identifying the commensal invertebrates.

SPECIES COMPOSITION OF BLUE MUSSEL POPULATIONS IN THE NORTHEASTERN GULF OF MAINE

PAUL D. RAWSON, SUSAN HAYHURST, AND BROOK VANSCOYOC
School of Marine Sciences, 5751 Murray Hall, University of Maine, Orono, Maine 04469-5751

ABSTRACT We examined the species composition of eleven blue mussel populations in eastern and central Maine, USA using a set of PCR-based genetic markers. Previous reports suggested that mussel populations in the Gulf of Maine were composed of only a single species, *Mytilus edulis*. In contrast, our results clearly indicate that the range of a congener, *M. trossulus*, extends well into the Gulf. The two blue mussels are sympatric in eastern Maine populations, including all of those we sampled within Cobscook Bay, ME. The frequency of *M. trossulus*, however, declines dramatically in the vicinity of Little Machias Bay, ME, so that populations along the coast of central Maine are composed predominantly of *M. edulis* mussels. Among populations containing a mixture of *M. edulis* and *M. trossulus*-specific alleles we observed a low but significant frequency of mussels with hybrid genotypes including putative backcross genotypes, indicating the potential for introgression between these two species. We suggest that larval supply and recruitment, thermal tolerance and perhaps the interplay of these factors likely delimit the southern extent of the range of *M. trossulus* and influence the species composition of blue mussel populations in the northwest Atlantic.

KEY WORDS: blue mussels, *Mytilus* spp., hybridization, biogeography, molecular markers

INTRODUCTION

Mussels in the genus *Mytilus* are widely distributed in the temperate and sub-polar zones of both the northern and southern hemispheres (Gosling 1992a) and are often dominant members of the rocky intertidal community. This genus includes a group of morphologically similar smooth shelled or blue mussels belonging to the *Mytilus edulis* species complex. Blue mussels have been the focus of a wide variety of studies on topics ranging from physiology, biochemistry, ecology, biogeography and pollution ecology, and are economically important as a source of food in many parts of the world (Gosling 1992a). Due to the lack of reliable morphological characters, the taxonomy of blue mussels has been highly confused historically. Based on the work of McDonald et al. (1991), however, who employed a combination of allozyme electrophoresis and multivariate analysis of morphological characters there are currently three recognized species of blue mussel worldwide, *M. edulis* (Linnaeus 1758), *M. galloprovincialis* (Lamark 1819), and *M. trossulus* (Gould 1850). In the northwest Atlantic, allozyme surveys have further indicated that *M. edulis* occurs from Cape Hatteras, NC to the Canadian Maritimes while *M. trossulus* has been observed at multiple locations in southeastern Nova Scotia and eastern Newfoundland, often in mixed populations with *M.edulis* (Koehn et al. 1976, 1984, Varvio et al. 1988, Bates and Innes 1995). Based on these surveys, it has been generally assumed that mussel populations within the Gulf are composed entirely of *M. edulis*.

The species composition of blue mussel populations in the northeast Gulf of Maine, however, had not been examined until Hennigar et al. (1996) used allozyme electrophoresis to assay variation at the mannose phosphate isomerase (*Mpi*) locus for mussels sampled from several sites in the Gulf, including the Bay of Fundy. The *Mpi* allozyme locus is considered to be the most diagnostic enzyme marker for identifying *M. edulis* and *M. trossulus* (e.g. Mallet & Carver 1995, Comesaña et al. 1999). Hennigar et al. (1996) observed a high frequency of *M. trossulus*-specific *Mpi* alleles at Digby, Nova Scotia and Hospital Island, New Brunswick, providing the first indication that the range of *M. trossulus* extends into the Gulf of Maine.

The presence of *M. trossulus* in this region is a serious concern to the Maine mussel culture industry. Although the mussel fishery in Maine has traditionally relied on harvesting from both natural beds and bottom culture leases seeded with juvenile mussels, the industry has recently begun to employ suspended culture systems. Reports from mussel farms in the Maritime Provinces of Canada suggest that *M. trossulus* mussels contain less meat than *M. edulis* mussels and their shells are prone to fracturing during processing (Freeman et al. 1994, Mallet and Carver 1995). Given species-specific growth rates, survival, and production losses, Mallet and Carver (1995) have estimated that, under raft culture conditions, the economic value of *M. edulis* is 1.7 times that of *M. trossulus*.

Blue mussels also figure prominently in environmental monitoring efforts within the Gulf of Maine. The Gulfwatch program, initiated in 1991 by the Gulf of Maine Council on the Marine Environment, assesses coastal habitat exposure to inorganic and organic contaminants by examining the accumulation of heavy metals, PCBs, and other toxins in mussels collected from 60 sites located between southern Massachusetts and Nova Scotia (Sowles et al. 1997). Significant differences have been observed in the seasonal patterns of lead, chromium, zinc, and mercury accumulation between *M. edulis* and *M. trossulus* (Mucklow 1996) emphasizing the need for accurate species identification and consideration of taxonomic affinity when interpreting data from the Gulfwatch program (Lobel et al. 1990, Sowles et al. 1997).

In this study, we set out to determine the southern-most extent of *M. trossulus*' range in the Gulf of Maine. Using a set of diagnostic molecular markers, we have assessed the species composition of eleven blue mussel populations sampled from central to eastern Maine. Recently, Bates and Innes (1995) and Comesaña et al. (1999) have used allozyme electrophoresis as well as DNA-based genetic markers to investigate the degree of hybridization between these two species and test hypotheses regarding the ecological factors which affect their distribution on the coast of Newfoundland. Although our study was not designed to specifically test for associations between species abundance and ecological factors, we compare our results to their findings to assess whether similar ecological and genetic mechanisms may be shaping the local distribution of and interaction between *M. edulis* and *M. trossulus* throughout the region where they are sympatric.

MATERIALS AND METHODS

Approximately 30 to 50 adult blue mussels (10.9–61.8 mm shell length) were collected from eleven locations along the coast of central and eastern Maine, including two separate sites near the Darling Marine Center (see Fig. 1). Sampling was conducted between February and July of 1999 at the lowest tide level during spring tides. Mussels from all twelve locations were transported live to the University of Maine were they were dissected. DNA was isolated from a tissue biopsy using the protocol of Schizas et al. (1997), wherein a small piece of mantle tissue (~10 mg) from each mussel was digested with 40 ng of proteinase K in 20 μl of a buffer containing 50 mM KCl, 10 mM Tris-HCl (pH 9.0), 0.1% Triton X-100 at 55°C for 3 hours. After the digestion process, the samples were heated to 95°C for 15 minutes and 20 μl of Gene Releaser (BioVentures Corp.) was added. The resulting slurry was incubated at 65°C for 30 s, 8°C for 30 s, 65°C for 90 s, 97°C for 180 s, 8°C for 60 s, 65°C for 180 s, 97°C for 60 s, 65°C for 60 s and centrifuged at 13,000 rpm for 2 min. The supernatant containing total cellular DNA was then removed to a new microcentrifuge tube.

Isolated DNA was used as template in each of four polymerase chain reaction (PCR)-based genetic assays. The application of the mt16S-F, Glu-5′, and ITS markers followed the protocols provided by Rawson and Hilbish (1995), Rawson et al. (1996a), and Heath et al. (1995), respectively. In this study, the use of the *Mytilus* anonymous locus 1 (MAL-1) marker essentially followed the protocol in Rawson et al. (1996b) except that the oligonucleotide primers were redesigned to amplify a smaller PCR product. Three of these markers, ITS, MAL-1, and Glu-5′, target the nuclear genome while the mt16S-F marker targets the mussel female mitochondrial DNA lineage. For each assay, 50 ng of template DNA was added to a 12.5 μl reaction (total volume) containing 50 mM KCl, 10 mM Tris-HCl (pH 9.0), 0.1% Triton X-100, 1.5 mM $MgCl_2$, 2.5 nmol dNTPs, 1 U *Taq* DNA polymerase (Promega) and 50 pmol of assay-specific forward and reverse oligonucleotide primers (Table 1). The reactions were initially denatured for three minutes at 94°C and then incubated for 30 cycles at 94°C for 30 s, followed by an assay-specific annealing temperature (see Table 1) for 30 s, and 72°C for 1 minute. The ITS, MAL-1 and mt16s-F markers relied on PCR to generate equal length PCR products for both *M. edulis* and *M. trossulus*. When these products were then digested with the appropriate restriction enzymes (see Table 1) species-specific restriction fragment length patterns were generated. For the Glu-5′ marker, which is similar to that designed by Inoue et al. (1995), PCR amplification produced *M. edulis* and *M. trossulus*-specific products that differ significantly in size (see Rawson et al. 1996a for details). For each marker the species-specific PCR products or PCR/RFLP fragments were resolved on 1.5% to 2.5% agarose gels.

Individual genotypes and haplotypes were scored as outlined for ITS in Heath et al. (1995), Glu-5′ in Rawson et al. (1996a), and mt16S-F in Rawson and Hilbish (1995, 1998). Although Rawson

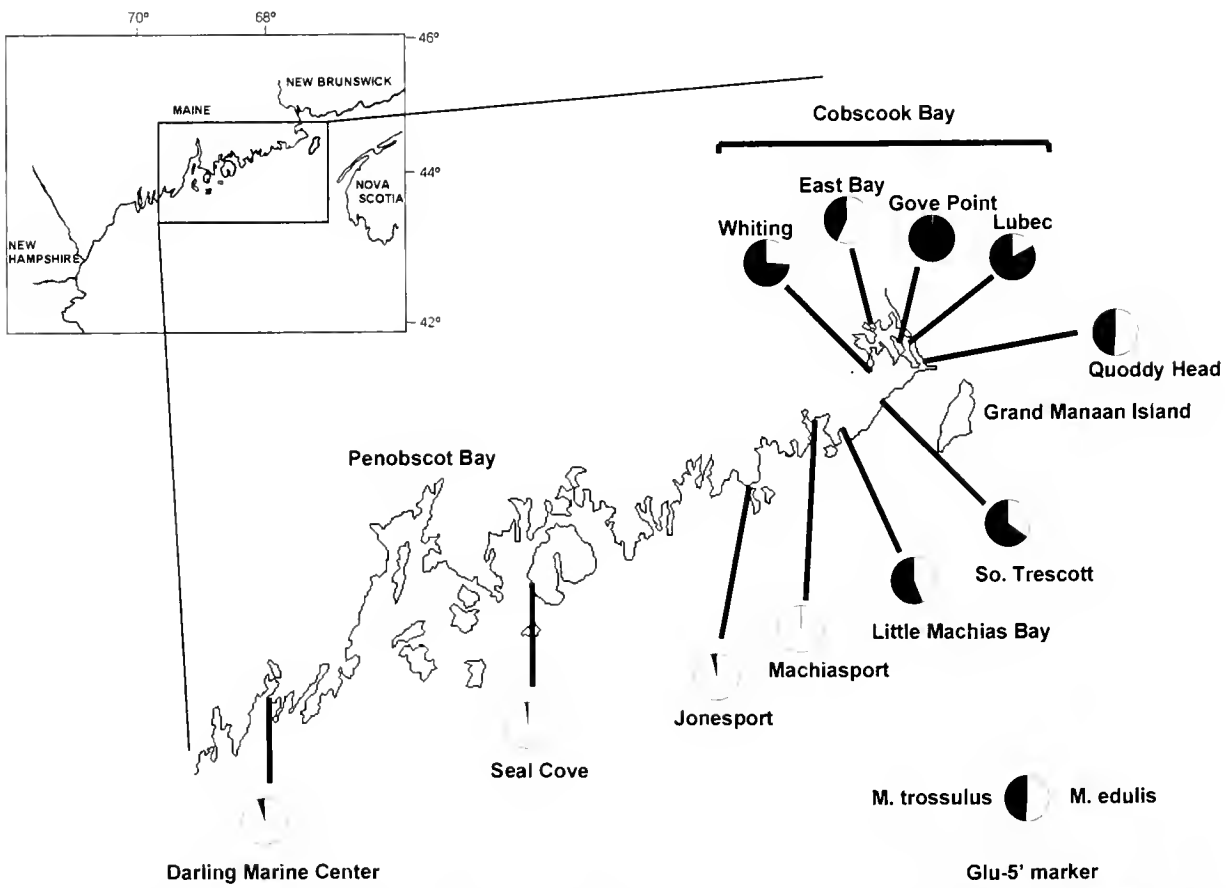

Figure 1. Map of the blue mussel populations in central and eastern Maine sampled in this study indicating the frequency of *Mytilus edulis* and *M. trossulus*-specific Glu-5′ alleles observed at each location. The frequency of Glu-5′ alleles at the two Darling Marine Center sites were combined for clarity.

TABLE 1.

Oligonucleotide primer sequences, annealing temperature, and restriction enzymes used in each of the four DNA-based markers employed in this study.

Marker	Primer Sequence	Temperature	Enzyme
ITS	Forward: GTTTCCGTAGGTGAACCTG Reverse: CTCGTCTGATCTGAGGTCG	50°C	*Hhal*
Glu-5′	Forward: GTAGGAACAAAGCATGAACCA Reverse: GGGGGGATAAGTTTTCTTAGG	57°C	NA
MAL-1	Forward: GAAGCGTATTTGGTCACTGGCAC Reverse: GTCATAAAATGGAACATCTGAGTC	50°C	*SpeI*
mt16S-F	Forward: CCGGTCTGAACTCAGATCACGT Reverse: CTGCCCAGTCGAACTAGAGTAAT	47°C	*SpeI* + *EcoRV*

et al. (1996b) described the application of the MAL-I marker for distinguishing *M. trossulus* and *M. galloprovincialis*, their study did not include *M. edulis*. As they reported, when MAL-I PCR products generated from *M. trossulus* DNA are digested with the restriction enzyme *SpeI* two different restriction profiles are observed. In contrast, when MAL-I PCR products generated from *M. edulis* DNA are digested with the same restriction enzyme, a single profile distinct from those observed for *M. trossulus* results (Fig. 2). Allopatric populations of *M. edulis* (Lewes, DE and Cape Anne, MA) and *M. trossulus* (Port Orford and Newport, OR) are fixed for alternate PCR/RFLP profiles at all four of these DNA-based markers (Table 2).

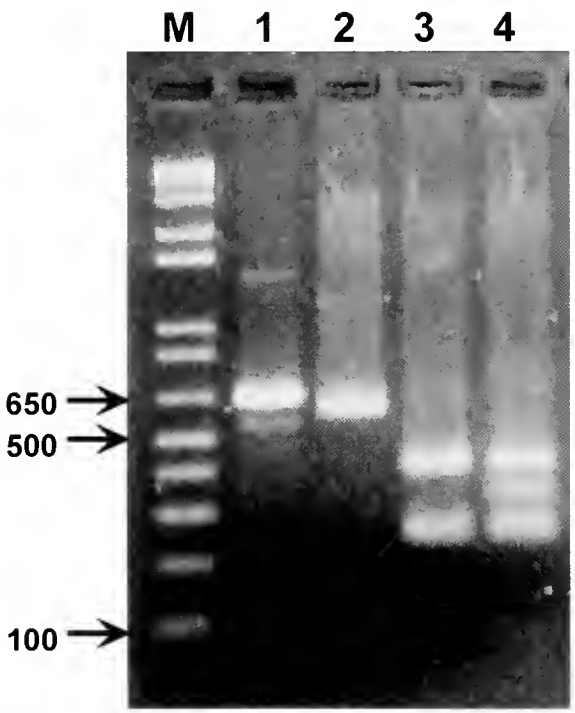

Figure 2. Restriction fragment length polymorphism for *M. edulis* and *M. trossulus* at the MAL-I locus analyzed on a 2.5% agarose gel. PCR amplification produces a single ~650 base pair band for both species as shown in the lane 1. Digestion of the PCR product produces a single banding pattern for *M. edulis* (lane 2) and two separate patterns for *M. trossulus*. Lane 3 shows the RFLP pattern for an individual homozygous for the T1 allele while lane 4 was produced by an individual heterozygous for the T1 and T2 alleles.

Allele and haplotype frequencies were estimated for each of the twelve sampling locations. Post hoc tests of heterogeneity were conducted using the allele frequencies at each locus to determine whether there were significant changes in the frequency of *M. trossulus*-specific alleles across all eleven study sites as well as across subsets of sites in eastern and central Maine. For each test, an R × C contingency table was constructed and an exact test for heterogeneity in allele frequency performed using the STRUC program distributed with the GENEPOP software package (Raymond and Rousset 1995). To estimate the frequency of mussels with multi-locus *M. trossulus*, *M. edulis* and hybrid genotypes, a hybrid index was constructed based on the number of *M. trossulus*-specific alleles a given individual carried at the ITS, MAL-I, and Glu-5′ markers. Thus, mussels homozygous for *M. trossulus* alleles at each nuclear marker received a score of 6, those homozygous for *M. edulis* alleles received a score of 0, while mussels with mixed multi-locus genotypes received a score between 1 and 5. For example, mussels which were heterozygous at two loci and homozygous for *M. trossulus*-specific alleles at the third locus received a score of 4. The frequency of mussels falling into each hybrid index score was estimated for the Whiting, East Bay, Gove Point, Lubec, Quoddy Head, South Trescott and Little Machias Bay samples combined. Each of these samples contained *M. trossulus* alleles at a frequency in excess of 5%.

RESULTS

We successfully genotyped 518 individual adult mussels (*Mytilus* spp.) for three, and in most cases, four PCR-based genetic markers. There was highly significant spatial heterogeneity in the frequency of *M. trossulus* and *M. edulis*-specific alleles and haplotypes across the 11 locations sampled in this study (Table 2). This was illustrated by the variation in the frequency of *M. trossulus* and *M. edulis* Glu-5′ alleles shown in Figure 1. In mussel populations east of the Little Machias Bay site, including all of the sites sampled in Cobscook Bay, *M. trossulus* alleles and haplotypes were quite common, with frequencies ranging from a low of 34.3% at South Trescott to a maximum of 97.4% at Gove Point. West of Little Machias Bay, however, the frequency of *M. trossulus*-specific alleles declined precipitously. There was no evidence of spatial heterogeneity in allele frequency for any of the four markers we employed among the Machiasport, Jonesport, Seal Cove, and both of the Darling Marine Center populations (Table 2) indicating that populations along the central coast of Maine consistently contained predominantly *M. edulis* alleles.

The observed spatial variation for each of the four markers was

[a] Genotypes at the ITS and Glu-5′ markers were scored as in Heath et al. (1995) and Rawson et al. (1996a) and for MAL-1 marker as described in the text. E = *M. edulis*-specific alleles and T = *M. trossulus*-specific alleles.

[b] Haplotypes at mt16S-F were scored as in Rawson and Hilbish (1995, 1998). A = *M. edulis*-specific haplotype and B = *M. trossulus*-specific haplotype.

[c] Tests for heterogeneity in allele/halpotype frequency were conducted across all sites as well as across sites within two regions, Eastern Maine (Whiting, East Bay, Gove Point, Lubec, Quoddy Head, South Trescott, and Little Machias Bay) and Central Maine (Machiasport, Jonesport, Seal Cove, Darling Center A and B).

*** $p < 0.001$.

NS not significant.

highly concordant (Table 2). This was further reflected by the predominance of mussels homozygous for *M. edulis* or *M. trossulus* alleles at all three nuclear loci. For each of the mixed populations containing appreciable frequencies of *M. trossulus* alleles (i.e. Whiting, East Bay, Gove Point, Lubec, Quoddy Head, South Trescott and Little Machias Bay), a hybrid index was calculated for each mussel based on the number of *M. trossulus*-specific alleles at each nuclear marker. Among the 320 mussels sampled from these seven sites, the vast majority (>87%) had index scores of 0 or 6, i.e. nearly all of the mussels sampled were homozygous for all three nuclear makers (Fig. 3). Less than 1% of the mussels we sampled had index scores of 3 and no mussel heterozygous at all three nuclear markers was observed. Of the remaining mussels, most (9%) had index scores of 4 or 5 indicating that these mussels carried more *M. trossulus*-specific than *M. edulis*-specific alleles. In addition, there was a high concordance between multi-locus nuclear genotypes and mitochondrial haplotypes. Of the 117 mussels with an index score of 0, all but one carried the A mt16s-F haplotype fixed in allopatric populations of *M. edulis*, while 161 of 163 mussels with an index score of 6 had the B mt16S-F haplotype found in allopatric populations of *M. trossulus*.

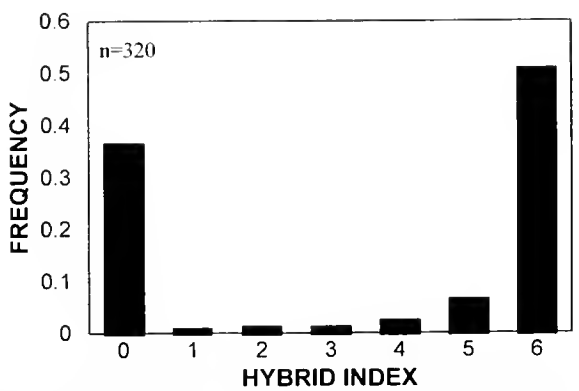

Figure 3. Frequency of mussels with multi-locus hybrid index scores based on the number of *M. trossulus*-specific alleles at each of three nuclear markers. A score of 0 indicates mussels homozygous for *M. edulis*-specific alleles at all three nuclear loci, a score of 6 indicates mussels homozygous for *M. trossulus*-specific alleles and scores of 1–5 indicate mussels containing a mixture of *M. edulis* and *M. trossulus* alleles. The analysis includes only mussels from the seven populations which contained >5% *M. trossulus*-specific alleles.

DISCUSSION

Our results indicate that a marked transition in the species composition of blue mussel populations occurs in the northeastern

Gulf of Maine. This contrasts with the conclusions of Koehn et al. (1976, 1984), who suggested that Gulf of Maine populations were composed solely of *M. edulis* mussels. Their studies, however, did not sample mussel populations between Bar Harbor in central Maine and Halifax on the eastern side of the Nova Scotian peninsula. Together with the results of Hennigar et al. (1996), who found high frequencies of *M. trossulus*-specific *Mpi* alleles in neighboring Passamaquoddy Bay, New Brunswick and Digby, Nova Scotia, our observation of fairly high frequencies of *M. trossulus* at several sites in eastern Maine, especially in the Cobscook Bay region, clearly indicates that mussels with *M. trossulus* alleles occur throughout the Bay of Fundy region and well into the Gulf of Maine.

Our results also suggest that there has been a limited amount of introgression between *M. edulis* and *M. trossulus*. Within populations containing appreciable frequencies of both *M. edulis* and *M. trossulus* alleles in eastern Maine, the vast majority of mussels had multi-locus genotypes consistent with their being pure *M. edulis* or *M. edulis* mussels. Among these multi-locus homozygotes (n = 280), all but three had species-specific mitochondrial haplotypes that were in agreement with their nuclear genotypes. For mussels with multi-locus hybrid genotypes, we found most to have hybrid index scores of 4 or 5, genotypes which are indicative of backcrosses formed by the mating of F1 hybrids with *M. trossulus* individuals. Thus, hybridization between *M. edulis* and *M. trossulus* to produce F1 mussels must occur, at least occasionally, even though we observed no tri-locus heterozygous mussels in our samples and the observation of putative backcross genotypes suggests that a low level of introgression occurs between these species.

A thorough analysis of introgression would benefit from additional nuclear markers (e.g. Boecklen and Howard 1997) and a more rigorous statistical framework (e.g. Nason & Elstrand 1993). From the reports presented to date, however, hybridization between *M. edulis* and *M. trossulus* appears to be relatively limited. Estimates of the frequency of hybrids ranges from a low of <2% (Mallet & Carver 1995) to as much as 23% in Nova Scotia (Saavedra et al. 1996) and 26% in Newfoundland (Comesaña et al. 1999). This level of hybridization is comparable to that reported by Rawson et al. (1999), Sarver and Foltz (1993) and Suchanek et al. (1997) for *M. trossulus* and *M. galloprovincialis* on the Pacific coast of North America. In contrast, several studies have reported a frequency of hybrids in excess of 50 to 80% at locations in Western Europe where *M. galloprovincialis* hybridizes with *M. edulis* (Sanjuan et al. 1994, Comesaña & Sanjuan 1997, Hilbish et al. 1994, Gardner 1996). Although many of these studies have employed different marker systems with varying ability to discriminate hybrid classes, taken together these observations are consistent with phylogenetic studies which suggest that *M. edulis* and *M. galloprovincialis* are sister taxa and *M. trossulus* is more distantly related to these other two taxa (Rawson & Hilbish 1998).

Gardner (1996) has proposed that differential adaptation to environmental conditions is the primary force determining the distribution of all three species of blue mussel, *M. edulis*, *M. galloprovincialis*, and *M. trossulus*, in the Northern Hemisphere. For example, within the most extensively studied blue mussel hybrid zone, several studies have shown that habitat-specific selection based on differential growth or physiology, strength of attachment to the substrate and other factors, plays a major role in the distribution of mussel genotypes across the region of sympatry between *M. edulis* and *M. galloprovincialis* in western Europe (e.g. Hilbish et al. 1994, Comesaña and Sanjuan 1997, see review by Gosling 1992b). Among the other blue mussel hybrid zones studied to date, the importance of differential adaptation is less well documented. Sarver and Foltz (1993) observed a correlation between local temperature and salinity and the distribution of *M. galloprovincialis* and *M. trossulus* on the Pacific coast of North America. Rawson et al. (1999), however, pointed out that hybridization between these two species occurs between Monterey and Cape Mendocino, California, a region that is characterized by extremely complex hydrodynamic conditions, so that limited dispersal may also be involved in determining the distribution of parental and hybrid mussels.

Likewise, in the northwest Atlantic it is presently unclear what mechanisms operate to structure the species composition of blue mussel populations. It has been suggested that *M. trossulus* may be better adapted to estuarine conditions and therefore is more tolerant of low salinity than is *M. edulis* (e.g. Gosling 1992b). Nearly all of the sites we sampled, including those with high frequencies of *M. trossulus* alleles, however, experience oceanic salinities (35 ppt) year round. The only exception was the Machias Bay population which was far enough upriver to occasionally receive pulses of fresh water. Yet, mussels at this site were fixed for *M. edulis* alleles and haplotypes. These results suggest that salinity cannot be the sole selective agent regulating the local distribution of *M. trossulus* and *M. edulis*. Bates and Innes (1995) and Comesaña et al. (1999) have also investigated the role of wave exposure in structuring mussel populations off the coast of Newfoundland. Their studies failed to find a clear association between the frequency of *M. trossulus* and degree of wave exposure in the populations they sampled. Similarly, we observed high frequencies of both *M. edulis* and *M. trossulus* alleles in all populations sampled in eastern Maine, including relatively sheltered sites within Cobscook Bay as well as the exposed sites on the outer coast such as Quoddy Head and South Trescott. Thus, neither salinity nor wave exposure is likely to explain the precipitous decline in the frequency of *M. trossulus* that we have observed in eastern Maine.

The spatial variation in the frequency of *M. trossulus* mussels that we observed among eastern Maine populations may reflect variation in larval supply and recruitment. Johnson and Black (1982) and Watts et al. (1990) suggested that genetic patchiness among populations of *Siphonaria sp.* and *Echinometra mathaei* were likely due to stochastic variation in larval recruitment. On a broader scale, regional current patterns can potentially limit larval dispersal and promote genetic divergence among conspecific populations. Although many population genetic surveys of marine species with highly dispersive stages have found little evidence to support the hypothesis that present day current patterns influence genetic divergence among contemporary marine populations (e.g. Benzie and Williams 1995, Shulman and Bermingham 1995), other studies such as those of Tracey et al. (1975) and Rocha-Olivares and Vetter (1999) observed that genetic structure for lobsters and rockfish, respectively, coincided with regional oceanic circulation patterns. In the Gulf of Maine, the Eastern Maine Coastal Current (EMCC) is a prominent oceanographic feature and is known to transport herring larvae from spawning grounds near Grand Manan Island westward along the coast of Maine (Townsend 1992). The EMCC also appears to have a significant influence on the distribution of *Alexandrium* sp., a dinoflagellate responsible for paralytic shellfish poisoning. The lowest incidence of paralytic shellfish poisoning along the coast of Maine occurs between the western edge of Penobscot Bay and Jonesport, ME (Shumway et al. 1988). In this region, *Alexandrium* is found pre-

dominantly offshore and its distribution coincides with an offshore-directed tongue of cold water near Jonesport (Dave Townsend, pers. comm.). The dispersive larval stage in blue mussels typically spans upwards of at least 3 to 4 weeks (Bayne 1976). Given a mean current velocity in the EMCC approaching 15–25 cm s^{-1} (Townsend 1992) there is the potential for any *M. trossulus* larvae entrained in the EMCC to be transported great distances to the west. Moreover, the offshore flow of the EMCC near Jonesport, ME is particularly evident in satellite imagery from the summer months (Fig. 4; see also Pettigrew et al. 1998) when the bulk of mussel larvae are in the water column along the coast of Maine. Thus, it is possible that any *M. trossulus* larvae transported west further into the Gulf of Maine may not be retained in nearshore waters at a time when they are competent to settle, and the relative strength and direction of the EMCC then, determines the extent to which the range of *M. trossulus* extends into the Gulf.

Temperature variation has also been investigated as a potential mechanism structuring the species composition of blue mussel populations in the northwest Atlantic (Mallet and Carver 1995). Given the broad-ranging distribution of *M. edulis*, the more restricted sub-polar distribution of *M. trossulus*, and the absence of *M. trossulus* from the Northumberland Straits between Prince Edward Island and New Brunswick, Canada, it has been suggested that the latter species is less tolerant of warmer waters (e.g. Gosling 1992b, Mallet & Carver 1995). Mallet and Carver (1995) examined the relative survival and growth of *M. trossulus* and *M. edulis* at two locations differing in mean temperature in Nova Scotia. Their findings, that *M. trossulus* demonstrated higher survival rates at the warmer site, were the reverse of what would be predicted based on the large scale distribution of *M. edulis* and *M. trossulus*. Their study, however, was limited to a comparison of the survival of adult mussels in two size classes (20–30 and 40–55 mm shell length).

In contrast, Bayne (1976) has argued that the environmental requirements for normal embryonic development are likely to be a major factor limiting the distribution of blue mussel populations. If so, then attempts to correlate adult distributions with spatial variation in environmental parameters are likely to be of limited value in determining the mechanisms regulating the species composition of mussel populations in the Gulf of Maine. More attention should be focused on processes affecting the early life history stages of mussels. In this regard, satellite imagery suggests that there may be a significant change in coastal water temperature along the coast of Maine, coincident with the offshore movement of the EMCC. East of Jonesport, where the EMCC remains close to shore, the nearshore waters remain relatively cool throughout the summer compared to those west of Jonesport. Thus, the EMCC may impact blue mussel larvae in two ways, in a direct manner wherein *M. trossulus* larvae are advected away from potential settlement sites and an indirect manner wherein the EMCC creates a temperature differential between eastern and western Maine that affects the survival of *M. trossulus* larvae. We have recently initiated a series of experiments designed to assess the relative importance of these two mechanisms in limiting the range of *M. trossulus* in Maine.

In conclusion, our results clearly show that *M. trossulus* occurs, and in some cases is the predominant species in mussel populations in eastern Maine. This study sampled two locations, Machiasport and Gove Point, frequently sampled by the Gulfwatch program (Hennigar et al. 1996). The marked change in species composition between these two sites illustrates the importance of monitoring the frequency of *M. trossulus* at Gulfwatch sites in the northeastern Gulf of Maine to facilitate the interpretation of Gulfwatch data. The findings of Mallet and Carver (1995) regarding the economic impact of *M. trossulus* on mussel aquaculture also highlight the importance of monitoring species composition at current and future mussel culture lease sites to enable the industry to select sites that limit the presence of this species. Additional work is now underway in our laboratory. We are attempting to better define the factors that control the distribution of *M. trossulus* throughout the Gulf of Maine, to further understand how the species composition of Gulf of Maine populations may change in the future.

ACKNOWLEDGMENTS

This research was supported by the University of New Hampshire/University of Maine Sea Grant program under contract 99-343 and Hatch funds provided by the U.S. Department of Agriculture and the Maine Agriculture and Forestry Experiment Station

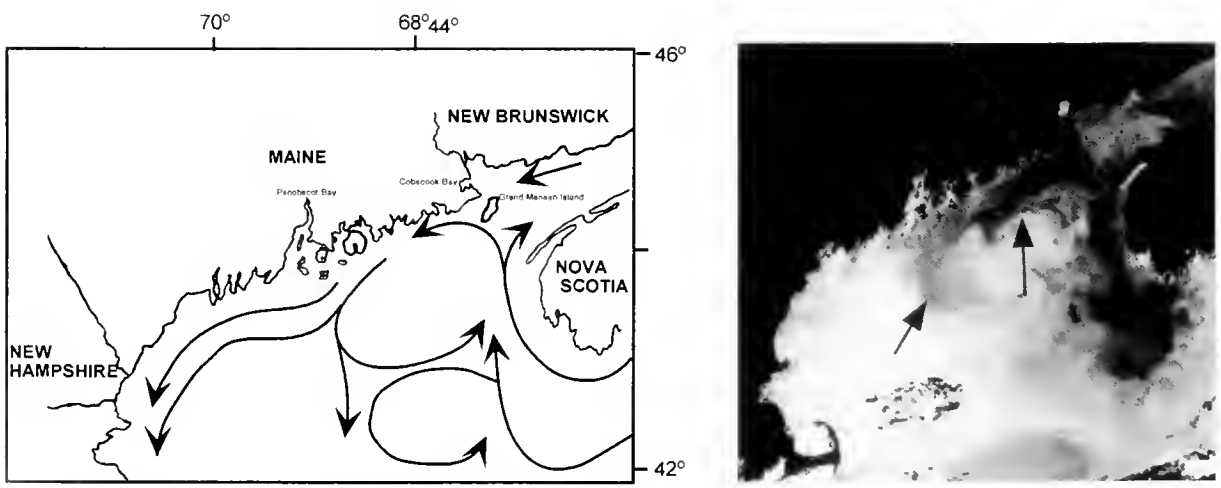

Figure 4. The map on the left provides a diagrammatic representation of the general circulation patterns (arrows) in the Gulf of Maine during stratified conditions typical in this region from May to September (after Pettigrew, unpublished). The figure on the right is an AVHRR satellite image of sea surface temperature in the Gulf of Maine on July 19, 1998. Cooler water appears as darker shades and warmer water as lighter shades in this image. The eastern Maine coastal current and an offshore-directed plume are indicated by the arrows. ABSTRACT The effect of temperature on reproductive maturity of recently spawned penshell broodstock *Atrina maura* (Sowerby 1835) was studied. Penshells were maintained in an open-flow system and were fed to satiation with a mixture of microalgae. Condition index (tissue wet weight/total wet weight × 100), the rate of maturation, and oocyte quality were followed histologically until spawning. A scheme of six stages, based on histological preparations, was found best to describe the maturation process in the penshell. Results indicate that penshell maturation must be at low temperatures over two months to obtain high quality oocytes in the hatchery, even though the maturation period can be shortened to half that time at higher temperatures. A reduction of the quality of oocytes is obtained at higher temperatures.

KEY WORDS: reproductive maturity, temperature, condition index, penshell, atresia, *Atrina maura*

INTRODUCTION

Along the Pacific coast of Mexico, five species of penshell bivalves occur (Keen 1971). *Atrina maura* (Sowerby 1835) is the species with the highest value adductor muscle. Over the past ten years, exploitation of penshell natural stocks has led to a decline in production (Velez-Barajas & Fajardo-León 1996, Cardoza-Velasco & Maeda-Martinez 1997). Penshells are vulnerable to overexploitation because they have a long life, limited reproductive investment, and sporadic recruitment (Butler et al. 1993). Because of the decline in production, an increased interest in the cultivation of *A. maura* was stimulated (Baqueiro & Castagna 1988, Arizpe-Covarrubias 1995, Reynoso-Granados et al. 1996). Information on the biology and aquaculture of *A. maura* is still scarce. In this species, tolerance to temperature and salinity and the optimum temperature for growth (Leyva-Valencia 1999), as well as the gonadic cycle in Bahia Magdalena (Maeda-Martínez unpublished data) and the growout method in the field (Cardoza-Velasco & Maeda-Martinez 1997) was determined. Two Mexican institutes (Centro de Reproducción de Especies Marinas in Sonora (CREMES) and at CIBNOR) produced a limited number of spat used mainly for scientific purposes. However, there are no studies on hatchery reproductive maturation of this species.

In other members of the family Pinnidae, such as *Pinna rugosa*, reproductive biology (Noguera & Gómez-Aguirre 1972, Coronel 1981) and recruitment (Arizpe & Félix 1986, Arizpe-Covarrubias 1987, Arizpe-Covarrubias 1995) was studied. Oogenesis and spermatogenesis have been described at an ultrastructural level in *Pinna nobilis* (de Gaulejac et al. 1995a, b), as having the ultrastructural changes of maturing oocytes in *Atrina pectinata* (Yongqiang & Xiang 1988).

Endogenous and exogenous factors control both gametogenesis and spawning (Barber & Blake 1991). Among the exogenous factors, the most important are temperature and food (Sastry 1963, Loosanoff & Davis 1963, Sastry 1966, 1968, Giese & Pearse 1974, Lowe et al. 1982, Taylor & Capuzzo 1983, Barber & Blake 1991). Mollusks can be caused to mature artificially out of season by increasing temperature and food (Loosanoff & Davis 1963). A threshold temperature is needed for vitellogenesis to continue and effects the transfer of nutrients necessary for the growth of oocytes (Sastry 1968, 1970, Sastry & Blake 1971, Blake 1972, Sastry 1979). The quality of oocytes can be assessed by the size of the oocytes at the postvitellogenic stage, and by examining oocyte morphology. The mean oocyte dimensions observed in histological sections is a reflection of the gametogenic cycle, because oocytes gradually increase in size as they develop, reaching maximum size prior to spawning (Barber & Blake 1991). However maximum size can vary depending on oocyte nutrition during vitellogenesis and therefore this size has to be determined experimentally under different exogenous conditions. Oocyte morphology is another criteria used to determine its quality. A common phenomenon usually observed in mollusks is oocyte degeneration (atresia) at the end of vitellogenesis because of the presence of lytic enzymes that spread throughout the acinus (Beninger & Le Pennec 1991).

To find the optimum temperature for reproductive maturation of recently spawned *A. maura*, we determined both the condition index and the rate of maturation and oocyte quality at different temperatures. As a basic reference, a histological study was done to describe the phases of reproductive maturation in this species.

MATERIALS AND METHODS

About 100 penshell (*A. maura*) specimens (98 ± 0.1 mm shell length) were brought to the laboratory at CIBNOR from the aquaculture farm Rancho Bueno, located at the southernmost end of Bahía Magdalena on the Pacific coast of Baja, 137 km northwest of La Paz. These animals were produced originally at CREMES and were then sent to Rancho Bueno for growout in Nestier trays suspended from a 100-m longline. By the time of collection on July 15, 1995, the animals were six months old and had fully developed gonads. Specimen spawning was easily induced in the laboratory by using a thermal shock. After spawning, the penshells were washed with seawater and divided randomly into three groups. They were then placed in three 1,500-L fiberglass tanks at 20, 25, and 30°C, vertically in plastic racks to simulate their natu-

*Corresponding author. E-mail: amaeda@cibnor.mx

ral position in the field. To eliminate an effect of food shortage on gonad maturation, microalgae was supplied continuously during the experiments. Each tank received a constant flow of 83-L h^{-1} of seawater at 37‰ salinity, containing a mixture of microalgae (*Isochrysis galbana*, *Monochrysis lutheri*, and *Chaetoceros gracilis*) at a concentration of 130–155 cells μL^{-1}. At this flow rate, the tanks received a daily water exchange of 133%. Counts of microalgae at the outlet ports of the tanks varied between 15 and 60 cells μL^{-1} depending on the number of animals held in the tanks throughout the experiments. The quality of these microalgae species on bivalve nutrition is well documented (Walne 1970). The water used in the experiments was drained from a 200-L tank where the cultured algae were mixed with flowing filtered seawater. The algae were kept well mixed in suspension by using an air bleed at the bottom of the tank. The mixture was monitored automatically with a Hach turbidimeter Model 1720C to make certain the algal concentration was constant. The turbidimeter operated a 1/32-hp submersible pump that transferred the microalgae to the mixing tank. The turbidimeter was set to turn on the pump when turbidity dropped below a preset value equivalent to the desired algal suspension of a standard calibration curve. The temperature in the 20°C tank was maintained with a 1/8 hp Acrytech water chiller. The temperature in the 25°C tank was held by setting the air conditioning system of the laboratory to that temperature, and the temperature in the 30°C tank was achieved by using six 200-W thermostatically controlled immersion heaters. The tanks were cleaned every day, removing feces with a plastic siphon hose.

To determine the influence of temperature on gonad maturation, six penshells were analyzed histologically at the start of the experiment and an equal number of animals from each tank was taken, and examined every 15 days (15, 30, 45, and 60 days). Tissues were fixed in Davidson's solution, dehydrated with an increasing concentration of ethanol (70% to 100%), and embedded in Paraplast at 56°C. Thin sections (6 μm) from the gonad area were cut with a rotary microtome and stained with hematoxylin and eosin (Howard & Smith 1983). From these sections, a schedule of the phases of gonad maturation in the penshell was termed. The quality of postvitellogenic oocytes at the different temperatures was evaluated by determining the nucleus-cytoplasm ratio and the presence or absence of atresia. The nucleus and cytoplasm of oocytes were measured with the Sigma Scan image analyzer software on images taken with a Zeiss light microscope Model 16. Only oocytes sectioned through the nucleolus were measured. Atresic oocytes were considered those in which the basophilic properties of the nucleus was lost, and the oocytes took a "jigsaw-puzzle" appearance (Barber and Blake 1991). Care was taken to record any spontaneous spawning in the tanks and also to fix for histological analyses the tissues of any specimen at the moment of spawning. The histological sections were used to define the different stages of gonad development in this species, taking into consideration morphology, presence of particular structures, and degree of vitellogenesis. Before cutting and embedding the tissues, a condition index was estimated by dividing the tissue wet weight of recently dissected animals by total wet weight, multiplied by 100.

RESULTS

Microscopic observations of gonadal sections from the different temperature treatments allowed us to determine that *A. maura* is a dioecious species with two previtellogenic (Stages I and VI), two vitellogenic (Stages II and III), one postvitellogenic (Stage IV), and one spent stage (Stage V) in the female gonad. Six stages were found that clearly describe spermatogenesis in the male gonad. We observed no hermaphroditism.

Female Gonad Maturation Stages

Stage I. Early Active

The acini are irregular in shape and are supported by interfollicular connective tissue (Fig. 1a). The acini stem cells give rise to primary oogonia 3–5 μm in diameter. The nucleus is round and contains a round nucleolus. In this stage, previtellogenic oocytes are round with a maximum diameter of 25 μm, and are attached to the acini.

Stage II. Developing

Acini walls are well defined and the interfollicular connective tissue has decreased (Fig. 1b). Acini acquired a circular shape with oocytes attached to the periphery. Oocytes enter the vitellogenic phase, which is evidenced by a rapid growth of the cytoplasm (lengthwise), reaching up to 60 μm in length. The nucleus also attains an elongated shape. It has a single nucleolus (5 μm) located centrally or marginally within the nucleoplasm. Oocytes are pedunculated and show dense aggregates in the stalk region, arranged in narrow rods perpendicular to the acini walls (Fig. 1c). These aggregates may correspond to the clusters of mitochondria arranged in line alongside cytoplasmic microtubules described by de Gaulejac et al. (1995a) in *Pinna nobilis*. Some elongated cells appear in the stalk region and are in close contact with the oocytes (Fig. 1d). These may play a role as auxiliary cells in the transfer of nutrients to the oocytes (de Gaulejac et al.1995a).

Stage III. Late Active

Oocytes continue to grow and attain a polyhedral shape (Fig. 1e) ranging from 45–57 μm in diameter. Some oocytes appear free in the lumen and others remain attached to the acini walls. The nucleus is round and occupies a large area in the middle of the oocyte. A dense amorphous mass (probably chromatin) is frequently observed in the nucleoplasm. The nucleolus decreases in size to 3.3 μm diameter, and appears surrounded by a nucleolar ring (Fig. 1e). From this stage on, a large and conspicuous dense aggregate (Fig. 1e) appears outside the nucleus, which may correspond to the 7–8 layered Golgi complex observed by Yongqiang and Xiang (1988) in *Atrina pectinata*. Auxiliary cells are no longer observed.

Stage IV. Mature

This stage marks the end of the vitellogenic process. Postvitellogenic oocytes measure a maximum of 56 μm along the major axis, and maintain their polyhedral shape because of oocyte crowding (Fig. 2a). Interfollicular and interoocyte spaces are minimal. Oocytes appear free in the lumen of the acinus. The dense aggregate still appears outside the nucleolar envelope.

Stage V. Spawning

Acini appear full of mature postvitellogenic oocytes with a broken germinal vesicle (Fig. 2 b). The dense aggregate and the nucleoplasm with the nucleolus appear spread along the ooplasm. The polyhedral shape is maintained because of oocyte crowding in the acini.

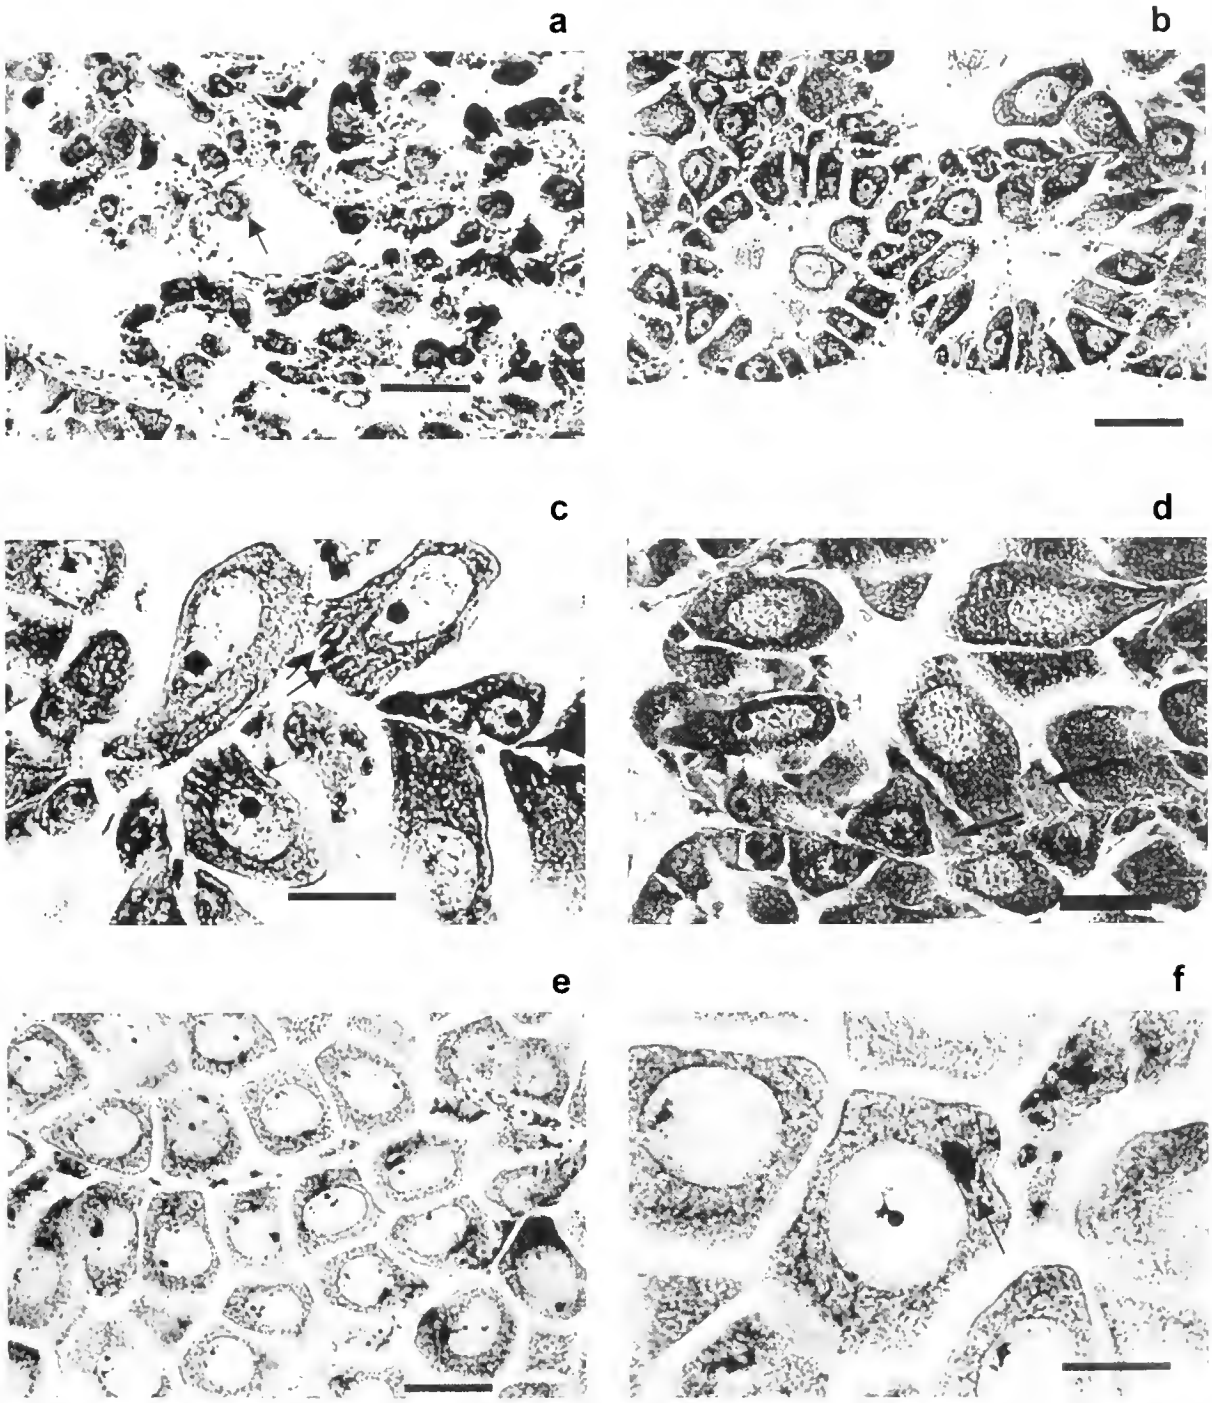

Figure 1. Light micrographs of stages of reproductive maturity in female *Atrina maura*, at 20° C. (a) Early active (stage I). Arrow shows an oocyte under formation within the acinus, bar = 50 µm. (b) Developing (stage II). Two acini with oocytes growing toward the lumen, bar = 50 µm. (c) Oocytes form stage II, showing clusters of mitochondria at the stalk, in line with microtubules (arrows), bar = 25 µm. (d) Oocyte from stage II with auxiliary cells at the stalk region, bar = 25 µm. (e) Oocytes at late active stage (stage III), bar = 50 µm. (f) Dense aggregate (arrow) on the external wall of nuclear envelope of a stage III oocyte, bar = 25 µm.

Stage VI. Spent

The acini are collapsed as a result of oocyte evacuation (Fig. 2c). A few unspent oocytes with the germinal vesicle intact remain in the acini in the process of degradation. Hemocytes proliferate during this stage, contributing to gonad repair.

Male Gonad Maturation Stages

Stage I. Early active

Acini look elongated (Fig. 3a). The germinal epithelium produces spherical spermatogonia 3-µm diameter after a centripetal

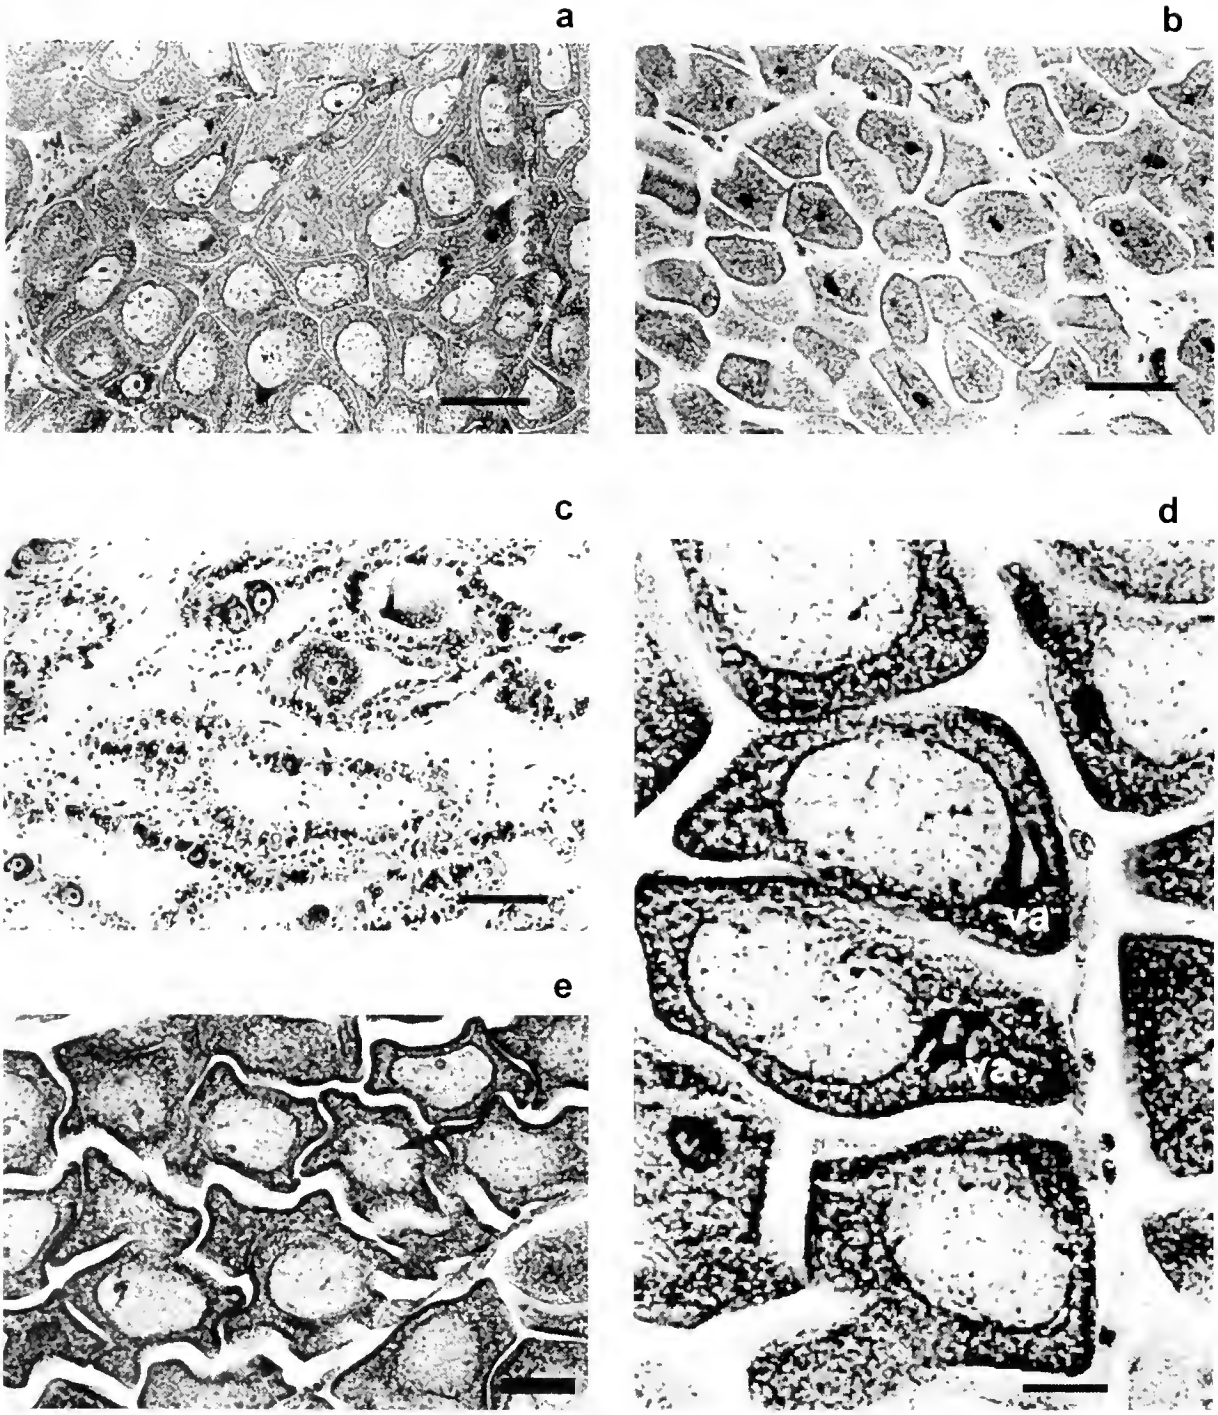

Figure 2. Light micrographs of stages of reproductive maturity in female *Atrina maura*. (a) Polyhedral oocytes at mature stage (stage IV) at 20°C, bar = 50 µm. (b) Oocytes at spawning stage (stage V) with broken germinal vesicles at 20°C, bar = 50 µm. (c) Spent gonad (stage VI) with residual non-spawned oocytes at 20°C, bar = 50 µm. (d) Overmaturated (atresic) oocytes (stage IV) showing vacuoles probably resulting from distension of endoplasmic reticulum at 30°C, bar = 25 µm. (e) Gonad with "jigsaw-puzzle" shaped overmaturated (atresic) oocytes (stage IV) at 30°C. Nuclei of some oocytes have lost their basophilic properties (arrows), bar = 20 µm.

evolution from the internal wall to the lumen. Spermatogonia are located along the internal wall of the acini in bands of several cells. Some spermatocytes are present in the lumen.

Stage II. Developing

Acini begin to show stratification (Fig. 3b), and all developmental stages are present including spermatogonia, abundant spermatocytes in the following layer, spermatids, and scarce spermatozoa located toward the acinus lumen. Cell diameter decreases from 3 to 0.5 µm.

Stage III. Late Active

Spermatogenesis takes place in the whole area of acini (Fig. 3c). The spermatogonia layer becomes thinner. The number of spermatozoa increase and their tails are directed toward the lumen.

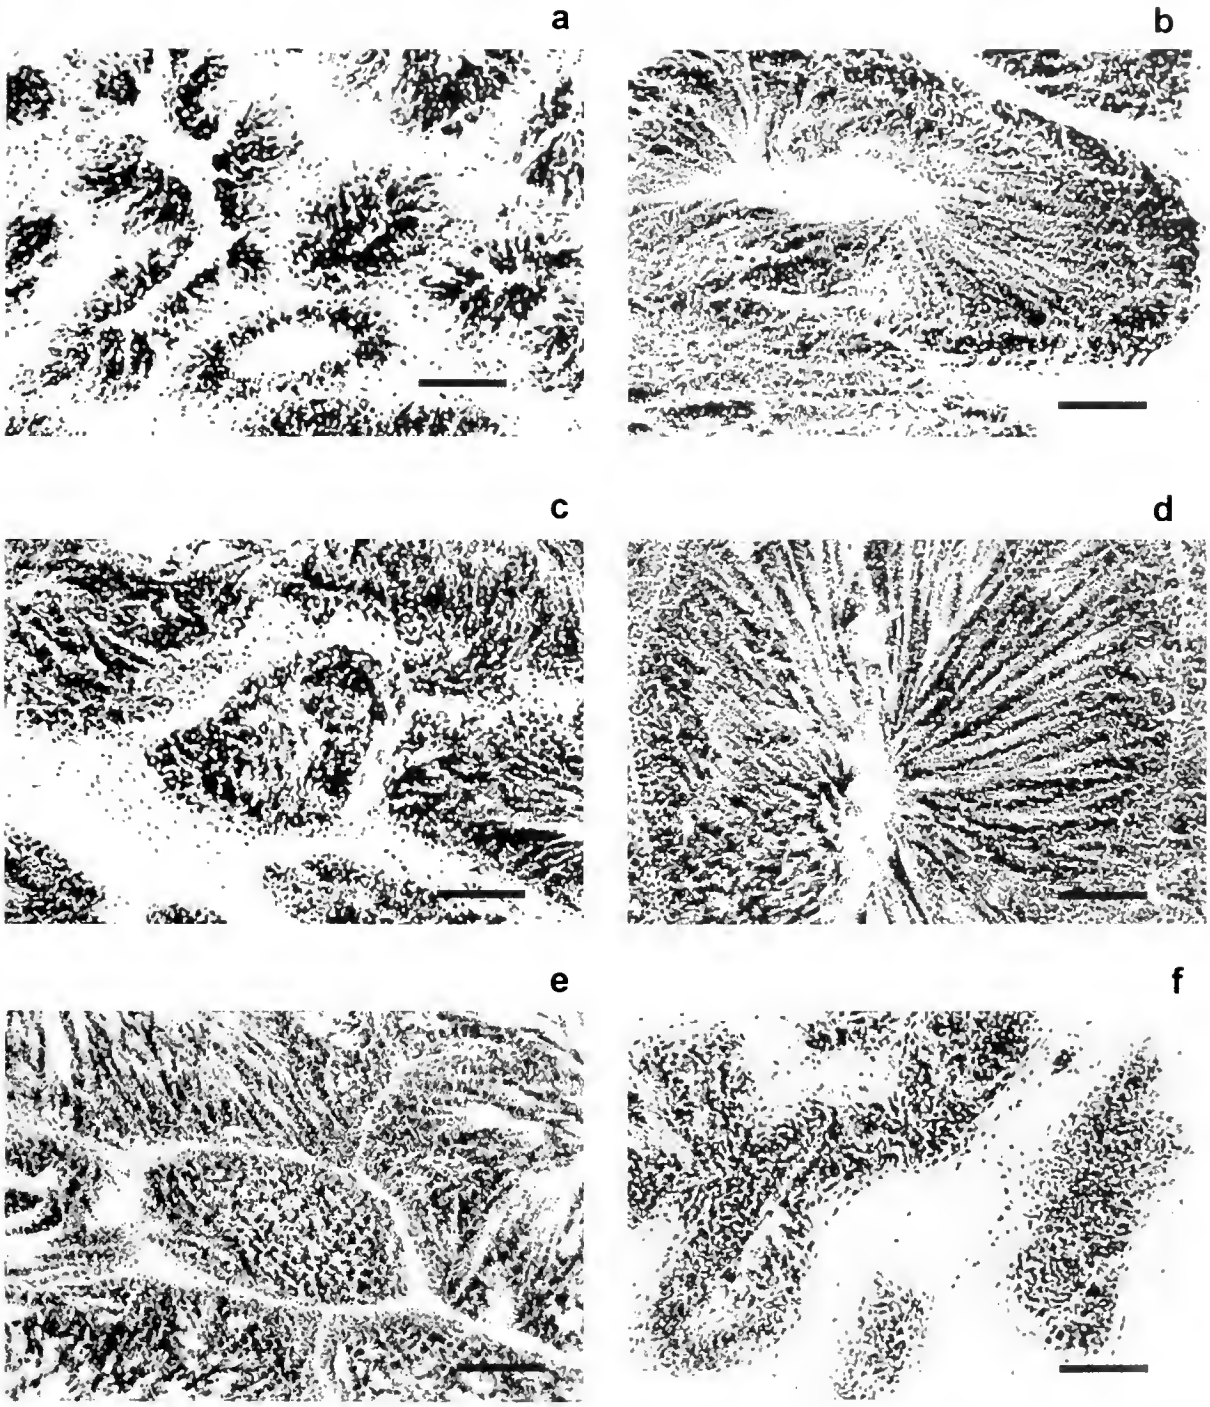

Figure 3. Light micrographs of stages of reproductive maturity in male *Atrina maura*, from 20 C treatment. (a) Early active (stage I) showing spermatoogonia at the periphery of acini, bar = 50 µm. (b) Developing (stage II), bar = 50 µm. (c) Late active (stage III), bar = 50 µm. (d) Mature (stage IV), bar = 50 µm. (e) Spawning (stage V), bar = 50 µm. (f) Spent gonad (stage VI) partially spawned, bar = 50 µm.

Stage IV. Mature

Acini look full of spermatozoa, with their tails toward the acini lumen (Fig. 3d). Merging of some acini is evident.

Stage V. Spawning

Acini become elongated and the boundaries between acini are not easily distinguished (Fig. 3e). Evacuating ducts are evident from which a great number of spermatozoa are spent.

Stage VI. Spent

Numerous empty spaces toward acini lumen are evident as a result of the release of spermatozoa during spawning (Fig. 3f). As in the female gonad, spawning is not complete. Some acini are empty but others remain full of ripe sperm. The empty acini show a great number of hemocytes. No signs of active spermatogenesis are observed in any region of the gonad.

Effect of Temperature on Maturation

The results of the histological analyses at different temperatures and sampling dates indicate synchronous gonad maturation in male and female gonads. In addition, a faster gonad maturation rate was observed at 25 and 30°C than at 20°C (Fig. 4). At the beginning of the experiments, more than 80% of the organisms showed immature gonads (stages I and VI) as a product of spawning induced by thermal shock. Only 20% were in stage II, indicating that gametogenesis can occur rapidly just after spawning. At day 15, samples from 20°C were only at stages I and II. At 25°C, 70% of the organisms were also in stage II, but the rest had reached developing stage III. At 30°C, the majority of the organisms (70%) were in stage III and the remaining 30% had reached maturity (stage IV). By day 30, a small proportion of animals (18%) at 20°C was still in stage II, but the rest had advanced to stage III. All specimens analyzed at 25°C had advanced to stage IV, but maturation rate in 30°C organisms did not show any progress. After this sampling date, spontaneous spawning was recorded at 25°C on day 34 and at 30°C on day 41. The results from spawning were only confirmed histologically on day 45 at 25°C, where 60% showed spent gonads. The remaining 40% had not spawned, showing gonads still in stage IV. Histological confirmation was not obtained at 30°C by day 45. In this treatment and date, relative frequencies remained the same as in days 15 and 30, with 70% and 30% in stages III and IV. Relative frequencies of penshells at 20°C on day 45 were 50% and 50% in stages II and IV. At 20°C, nearly 80% of the organisms were in stage III and the rest in stage IV on day 60, and spawning of these organisms was also recorded on day 60.

Oocyte Size and Nucleus-Cytoplasm Ratio

Results from postvitellogenic oocyte measurements at different temperatures are shown in Table 1. From this, oocytes at 20°C show on average a larger area (1660 μm^2) and major axis (56 μm) than those at 25°C (1416 μm^2 and 53 μm) and 30°C (1290 μm^2 and 49 μm). ANOVA indicates a significant difference between oocyte sizes at different temperatures at $\alpha = 0.05$. A Tukey's multiple range test showed that oocyte areas at 25 and 30°C were similar at $\alpha = 0.05$, but were significantly different from those at 20°C.

The areas of the nucleus varied between 578 and 564 μm^2 at different temperatures, but the ANOVA identified no significant differences between temperatures. With these data, we calculated a nucleus-cytoplasm ratio that was lower (0.34) at 20°C than at 30°C (0.43). This indicates a reduction in cytoplasm area at higher maturation temperatures.

Atresia

A second way to demonstrate oocyte quality related to maturation temperature was the presence of atresic oocytes. Results from histological observations indicate that atresic oocytes were not present in animals held at 20°C but were observed in stage III and IV female gonads at 25°C and 30°C (Fig. 2e). In this Figure, one can see the nucleus of atresic oocytes has lost its basophilic properties, and the oocytes have a "jigsaw-puzzle" appearance. Atresic oocytes were smaller than normal oocytes. The cytoplasm of nonatresic oocytes at 25 and 30°C showed large vacuoles (Fig. 2f) at the dense aggregate outside the nucleus. Vacuolation of this kind was reported in atresic oocytes of *Pinna nobilis* (de Gaulejac et al. 1995a), as a result of distension of endoplasmic reticulum.

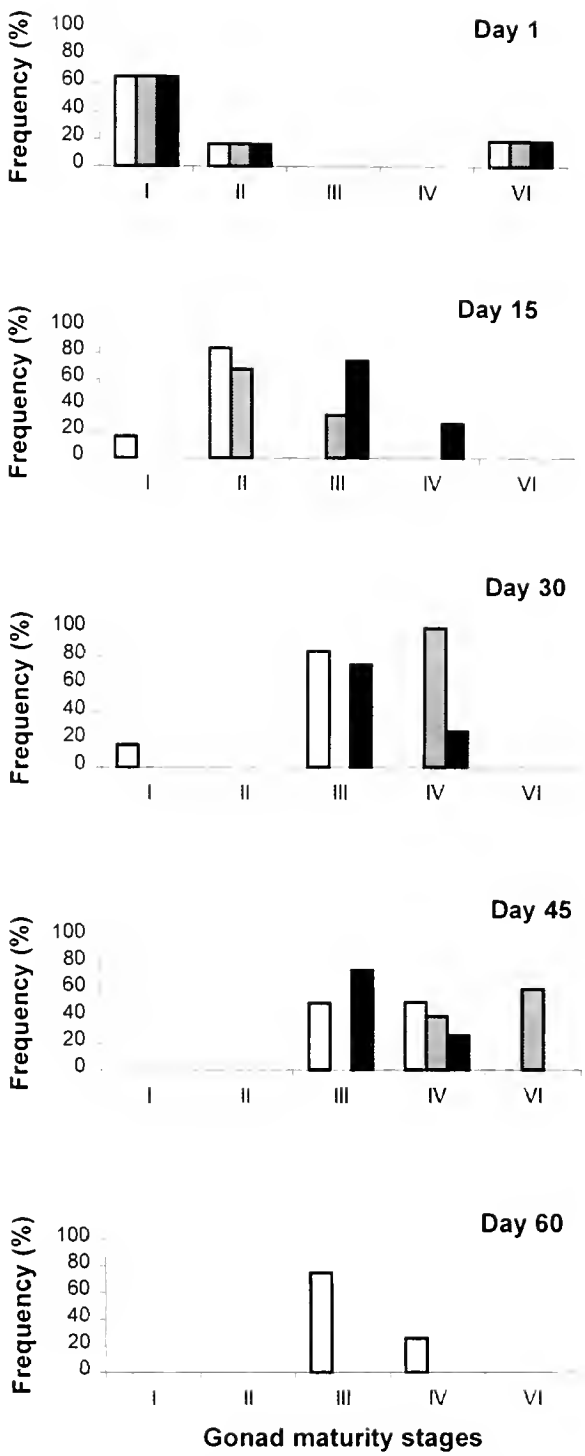

Figure 4. Relative frequency of stages of reproductive maturity in *Atrina maura*, at different maturation times and temperatures (white columns = 20°C, gray columns = 25°C, black columns = 30°C).

Condition Index

Condition index (CI) at 20°C increased steadily from 32% at the beginning of the experiment to 52% at day 60 when spawning occurred (Fig. 5). However, at 25°C and 30°C, only small increases were measured during the maturation period. At these temperatures, CI increased rapidly from 32% to 38% in the first 15

TABLE 1.

Dimensions of postvitelogenic oocytes and nucleus of penshell (*Atrina maura*) and the nucleus-cytoplasm ratio (N:C), at different temperatures.

Temperature (°C)	Oocyte			Nucleus			N:C Ratio
	Area (μm^2)	Major Axis (μm)	Minor Axis (μm)	Area (μm^2)	Major Axis (μm)	Minor Axis (μm)	
20	1660 ± 300	56 ± 6	42 ± 6	578 ± 101	31 ± 3	25 ± 3	0.34
25	1415 ± 182	53 ± 4	39 ± 5	564 ± 83	31 ± 3	24 ± 3	0.39
30	1290 ± 234	49 ± 6	37 ± 5	564 ± 110	30 ± 3	24 ± 3	0.43

Figures are the mean ± standard deviation (n = 90).

days, but no further increases were observed from day 15 to day 30 at both temperatures. From days 30 to 45, minor increases of 1% and 8% were recorded at 25°C and 30°C. Spawning at these temperatures occurred at days 34 and 41. No effect of spawning on CI was detected at these temperatures.

DISCUSSION

In the literature, many schemes for classifying gonad condition in mollusks can be found (Chipperfield 1953, Lubet 1957, Sastry 1963, Wilson & Hodgkin 1967, Lunetta 1969, Seed 1969, Villalejo-Fuerte & Ochoa-Báez 1993, de Gaulejac et al. 1995a, de Gaulejac et al. 1995b, Villalejo-Fuerte et al. 1995). We developed a specific scheme for *Atrina maura* based on morphological observations of gametes and specific structures. The scheme developed included six stages that clearly describe the gonad maturation process in *A. maura*. Although our work was conducted using light microscopy, interpretation of several structures was possible using the ultrastructural descriptions of gonad maturation made by Yongqiang and Xiang (1988) and de Gaulejac et al. (1995a,b), for the pinnids *Atrina pectinata* and *Pinna bicolor*. This study revealed maturation of male and female gonads occurs synchronously, and progressed evenly among the animals in the same treatment.

Morphological observations allowed us to compare the oocytes of *Atrina maura* with those described in *A. pectinata* and *Pinna nobilis*. Results indicate that the oocytes of *Atrina* species are morphologically similar, but three interesting differences exist with the oocytes of *P. nobilis*. The margin of the nucleus of *P. nobilis* is polylobed and twisted, whereas in *Atrina* the nuclear envelope is even and lacks indentations throughout development. The nucleolus in *P. nobilis* is located at the edge of the nucleus, whereas in *Atrina* it can either be at the edge or in the center. Finally, the dense aggregate (presumably a Golgi complex) found outside the nucleus of *Atrina* oocytes is not conspicuous in *P. nobilis*.

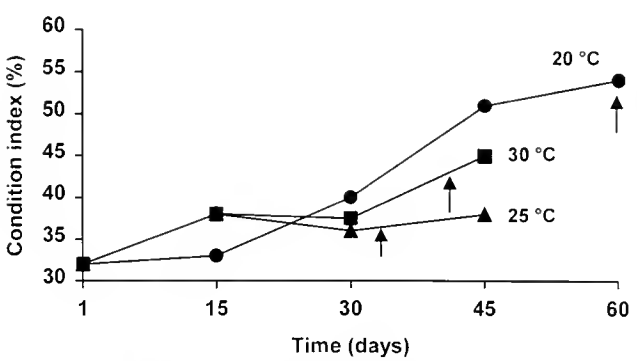

Figure 5. Changes in condition index of *Atrina maura* at different temperatures. Arrows indicate the day of spontaneous spawning.

Previous studies on the reproductive biology of bivalve mollusks have demonstrated that temperature and food are the most important factors influencing the reproductive cycle of marine invertebrates (Loosanoff & Davis 1963, Sastry 1963, Giese & Pearse 1974, Lowe et al. 1982). We found an effect of temperature on the rate of gonad maturation and the quality of oocytes in *A. maura*. The effect of food on these factors was eliminated by feeding the organisms to satiation with high quality species of microalgae in all treatments. Differences in the rates of gonad maturation and quality of oocytes are therefore attributed exclusively to temperature. The gonad maturation period was shorter at 25°C and 30°C than at 20°C, possibly because of the higher metabolic rates found at higher temperatures in this species. The scope for activity and shell growth rate measurements indicate the range of optimum temperature for growth in juvenile *A. maura* was 25–29°C (Leyva-Valencia 1999, Leyva-Valencia et al. 2001). With this knowledge, and desiring the shortest conditioning period possible, we suggest that penshell gonad maturation should be done at a temperature above 25°C. However, the results from histological observations on the quality of oocytes may lead to a different conclusion. Larger and nonatresic oocytes were only found at 20°C, probably because of a longer vitellogenic phase that allowed the incorporation of larger amounts of nutritive materials. Spawning from unfed or stressed broodstock results in weak batches of larvae that fail to undergo normal pelagic development (Loosanoff & Davis 1963, Bayne et al. 1984). The correlation between both factors on the fecundity and larval viability in *A. maura* needs to be determined. Coincidentally, spawning of *A. maura* in Bahía Magdalena takes place during the coldest season of the year (from January to March) when water temperature varies between 19.5 and 20°C (Maeda-Martínez unpublished data).

We measured condition index (CI) based on tissue and total wet weights of the animals. This is not a refined method but it proved to be a good alternative for measuring CI in *A. maura*. One of the problems that limited the use of a more precise method was the gonad in this species is included in a visceral mass together with other tissues, and it is not possible to obtain its weight excluding other tissues. Clear differences were observed between CI from the different temperature treatments and these correlated positively with oocyte size. Therefore, CI reflected variation in gonad size assuming that fecundity was the same among treatments. This means that smaller ("immature") oocytes were spontaneously spawned at 25°C and 30°C. The lower cytoplasmic content in

these oocytes was confirmed with the results from the nucleus-cytoplasm ratio. The relation between oocyte size and viability of resulting penshell larvae and spat remains to be tested.

Another factor that may have contributed to the depletion of CI at higher temperatures (25–30°C) was the formation of atresia. CI depletion was observed after the first 15 days from the start of the experiments (Fig. 5) at the beginning of vitellogenesis when atresia normally occurs (Barber & Blake 1991). The acceleration of maturation at high temperatures (25 and 30 C) resulted in necrotic oocytes, probably by the secretion of lytic enzymes (Beninger & Le Pennec 1991). Prolonged exposure of *Argopecten irradians* to subthreshold temperature, with oocytes undergoing vitellogenesis, results in vacuolization of the cytoplasm as we observed in *A. maura* (Fig. 2d) and lysis of oocytes (Sastry 1966, 1968). Although oocyte degeneration is a commonly observed phenomenon in species whose gametogenesis is under the control of natural environmental conditions (Pipe 1987), further studies are needed to find the correlation between temperature and secretion of lytic enzymes. Temperature did not affect the morphology of male gonads. Again, the viability of sperm released from animals matured at different temperatures remains to be tested.

In conclusion, results from the present work indicate that to obtain high-quality oocytes in the hatchery, penshell maturation must be done at low temperatures (20°C) over two months. Even though the maturation period could be shortened to half this time at higher temperatures, the quality of oocytes is greatly reduced.

ABSTRACT Halotolerance, upper thermotolerance, and optimum temperature for growth was investigated in juvenile penshell (*Atrina maura*). Halotolerance and thermotolerance were determined measuring LD_{50}-96h within the salinity and temperature ranges of 15–50‰ and 19–35°C. Optimum temperature for growth was measured estimating scope for activity, ingestion, and clearance rates at 16, 19, 25, and 29°C. Growth rates were also measured over 42 days at the same temperatures. Results indicate that salinity LD_{50}-96h ranged from 16‰ to more than 50‰, and the upper temperature LD_{50}-96h was 33.2°C. Scope for activity, ingestion, clearance, and growth rates were highest at 29°C indicating that optimum temperature in penshell juveniles is 29°C or higher. Because of the wide halotolerance range and the high thermotolerance and optimum temperature, the penshell is a good candidate for aquaculture in subtropical and tropical areas.

KEY WORDS: *Atrina maura*, penshell, salinity tolerance, temperature tolerance, temperature optimum

INTRODUCTION

The penshell *Atrina maura* Sowerby, 1835, is a bivalve mollusk that lives in shallow coastal lagoons and estuaries along the Pacific coast from Baja California to Peru (Keen 1971). It has a large adductor muscle of great value in Mexican and international markets. Natural populations in Mexico have decreased because of overfishing (Reynoso-Granados et al. 1996). Because of this, there is an increasing interest to develop aquacultural techniques for this species. Aquacultural methods are under development (Maeda-Martínez et al. 1996). It appears that a combination of suspension culture for the nursery stage and bottom culture for growout will be adequate for the species (Reynoso-Granados et al. 1996, Maeda-Martinez, A.N. unpublished results). Growout in bottom culture lasts two years (Cardoza-Velasco 1998), allowing then harvesting of meats of 14–26 g fresh weight (Cardoza-Velasco unpublished results) at 9–11USD/kg in the Mexican market (Velez-Barajas and Fajardo-León 1996, Cardoza-Velasco 1998).

The tolerance limits to salinity and temperature and the optimum temperature for growth have not yet been determined. For *A. maura*, knowledge of the limits of these variables are important to optimize hatchery production and to select sites for aquaculture in the field. Tolerance limits have been determined in other mollusks (Al-Habbib & Graingner 1977, Wilson 1978, Ansell et al. 1980, Ansell et al. 1981, Poza-Boveda & Rodriguez 1987, Quinn et al. 1994, Sicard-González 1999).

Physiological methods such as scope for activity and clearance and ingestion rates are good tools to determine optimum values, as these correlate well with actual growth measurements (Sicard et al. 1999). Scope for activity has been used as a good indicator of the energy available to the organism to do other functions, apart from basic maintenance, such as growth, reproduction, movement, and regulation against variations in external factors (Fry 1947). Scope for activity is the arithmetic difference between active and standard respiration rates. The former is obtained from an individual fed to satiation and the latter from an organism kept under long-term starvation. Under starvation, respiration rate gradually drops to a steady-state in several days. Scope for activity is then determined over a wide range of temperatures, and the optimum value would be where the difference between active and standard respiration rates is a maximum.

Other physiological factors such as clearance and ingestion rates have been found in the catarina scallop to correlate with scope for activity over a wide range of temperatures (Kirby-Smith 1970, Lu & Blake 1997, Sicard et al. 1999). This needs to be confirmed because optimum values for growth could be determined in the future by making only clearance rate experiments.

In the present work, tolerance limits to salinity, the upper tolerance limit of temperature, and the optimum temperature for growth of penshell juveniles have been studied.

MATERIALS AND METHODS

Experimental Animals

Penshell (*A.maura*) juveniles were produced in the hatchery at CIBNOR following a technique developed by Robles-Mungaray (unpublished results). These were approximately 5-months old when used, and measured 23 ± 10 mm shell height. To standardize the results, the relationship between shell height and dry tissue weight of 24 juveniles of the size range used in the experiments was calculated. Shell height was found to be a better characteristic than shell length, because the shell margin could be easily damaged during measurements. To obtain the dry weight of the tissues, the whole animals were dried in an oven at 65°C for 36 h and then the tissues removed from the valves with a dissection needle. The tissues were weighed on an electronic OHAUS microbalance, model Galaxy 110 with 0.1 mg resolution.

Halotolerance and Upper Thermotolerance

Halotolerance of penshell juveniles was determined following the standard procedure of LD_{50}-96 described by Rand and Petrocelli (1985). This consists of recording survival at predetermined times up to 96 h in animals exposed to a range of a given variable, i.e. temperature, salinity, toxic substance. Before the experiments, the juveniles were maintained for 14 days in 70-L plastic tanks containing 40 L of seawater at 22°C and 38‰ salinity. During this acclimation period, the tanks received constant aeration and the animals were fed 4×10^9 cells/penshell/day of a 1:1 mixture of the

*Corresponding author. E-mail: amaeda@cibnor.mx

microalgae, *Isochrysis galbana* and *Chaetoceros gracilis*. Fifty percent of the water was changed every day.

At day 14, groups of seven juveniles, in triplicate, were transferred from the acclimation tanks to 3.5-L containers with seawater at 22°C and at 15, 20, 25, 30, 38, 42, 45, and 50‰ salinity. The water for salinity treatments below 38‰ was prepared by diluting seawater with distilled water, and those at higher salinity with sea salts added to give the desired salinity. During the experiments, 50% of the water was changed daily and the animals were fed with the same mixture of microalgae. Survival was recorded at 4, 8, 72, and 96 h.

Upper thermotolerance was determined in penshell juveniles following the same method for halotolerance. The range investigated was 19°C to 35°C. Groups of seven juveniles in triplicate were transferred to the 3.5-L containers with water at 38‰, and at 19, 22, 24, 28, 30, 32, and 35°C. The 19°C treatment, which was colder than the temperature in the laboratory (22°C), was achieved by placing the containers in a refrigerated waterbath, and in the rest of the treatments, a 200-Watt thermostatically-controlled heater was introduced to each container. The water was constantly aerated to assure good mixing. Fifty percent of the water was changed daily and the animals were fed with the same mixture of microalgae used in the previous experiments. Survival was recorded at 4, 8, 72, and 96 hours.

Optimum Temperature

Optimum temperature of penshell juveniles was determined by measuring the scope for activity, and the rates of clearance, ingestion, and growth. Groups of five bivalves in triplicate were transferred to 19-L cylindrical tanks containing sea water at 38‰ and ambient temperature (22°C). The water of these tanks was gradually adjusted to the experimental temperatures (16, 19, 25, and 29°C) changing the temperature 1°C/day. Temperatures of 16 and 19°C were produced by dipping the tanks into a 1,100-L fiberglass tank, connected to a 1-hp titanium water chiller recirculating the water. In those treatments warmer than 22°C (25 and 29°C), a 200-Watt thermostatically controlled heater was introduced into each tank. Once all treatments were at the correct temperatures, a 10-day acclimation period was given, feeding the penshells a mixture of 3.6×10^7 cells/individual/day of *I. galbana* and *C. gracilis* in a 1:1 proportion. Half of the water volume was changed every day.

Scope for Activity

Scope for activity is the arithmetical difference between active and standard O_2 uptake rates. In this work, active respiration rates were measured by incubating, for 30 min, groups of five acclimated animals in 300-mL BOD bottles filled with O_2-saturated seawater at the experimental temperatures and 38‰ salinity, in triplicate. The volume of the bottles was determined at each experimental temperature by calculating the difference between the weight of the bottle filled with distilled water, minus the weight of the empty bottle. The seawater was previously filtered through a 0.75-μm GF/F membrane to reduce respiration from other organisms. Three bottles treated in the same manner without animals served as controls. After incubation, the oxygen content (PO_2) of the bottles was accurately estimated by determining the PO_2 of four subsamples of water siphoned into ground-neck borosilicate glass tubes of approximately 7 mL. Subsamples were fixed for further O_2 determinations following the method of Maeda-Martínez (1985). This method uses a miniaturized version of a micro-Winkler titrator developed by Bryan et al. (1976). This titrator has been used by Sicard et al. (1999) with good results.

Active O_2 uptake rate (AVO_2) was calculated with the equation

$$AVO_2 = \frac{PO_{2i} - PO_{2f}}{\Sigma DTW \times 0.5\ h}$$

where PO_{2i} is the oxygen concentration in the controls, PO_{2f} is the oxygen concentration in the incubated bottles, Σ DTW is the dry tissue weight of juveniles incubated, and h is the incubation time in hours. Once the active rates were determined, the animals were transferred to their original acclimation tanks, and were kept at the same conditions as before, but without the addition of food. The VO_2 of the organisms from all treatments was frequently measured, observing a gradual decline in VO_2, until a minimum stable level was reached. This level was equal to the standard respiration rate (SVO_2). The scope for activity of the penshell juveniles was calculated by $AVO_2 - SVO_2$ at the different temperatures tested. A one-way analysis of variance (ANOVA) was done to find significant differences of AVO_2 and SVO_2 at different temperatures. A Tukey's test was applied to find similarities among temperature treatments. Optimum temperature was where the difference was a maximum.

Ingestion and Clearance Rates

Ingestion rates (IR) and clearance rates (CR) were measured following the principle of the method of Winter (1973). This estimates IR and CR from the amount of algae removed by the animals incubated at a constant algal concentration. In this way variations on feeding rates because of a decrease in food concentration are eliminated. The amount of algae cleared by the animals is calculated from the algae replenished into the incubating chamber as removal occurs. Replenished algae will be equivalent to the algae consumed. In the present work we used a system that operates under this principle (Sicard et al. 1999) (Fig. 1), based on the design of Gallager and Mann (1980). Five juveniles of *A. maura* were incubated in a 1-L cylindrical chamber containing seawater filtered at 7 μm at the same experimental temperatures of the scope for activity experiments, 38‰ salinity, and 8×10^4 cells/mL of *I. galbana*. The water was pumped to a flow-through cell of a Turner 112 fluorometer with a peristaltic pump at 87 mL/h. The fluorometer was optimized for chlorophyl *a* readings by using a 47B filter and 420–500 nm wavelength. The relationship between microalgae concentration (MC) (cells/μL) and the fluorometer output voltage (Volts) was described by the linear regression equation ($R^2 = 0.98$; $n = 10$)

$$MC = 226 \times Volts - 22.3$$

The water from the cell was returned to the incubation chamber. When the algal concentration dropped, the system operated a second peristaltic pump which transferred concentrated microalgae to the chamber at 1.0 mL/min until the concentration was reestablished. The algae in the chamber were kept homogeneous in suspension with an air bleed. The system recorded the volume of algae pumped (V) during a 2-h incubation time (t). IR (cells ingested/g DTW/h) was then calculated with the equation

$$IR = \frac{V \times S}{\Sigma DTW \times t}$$

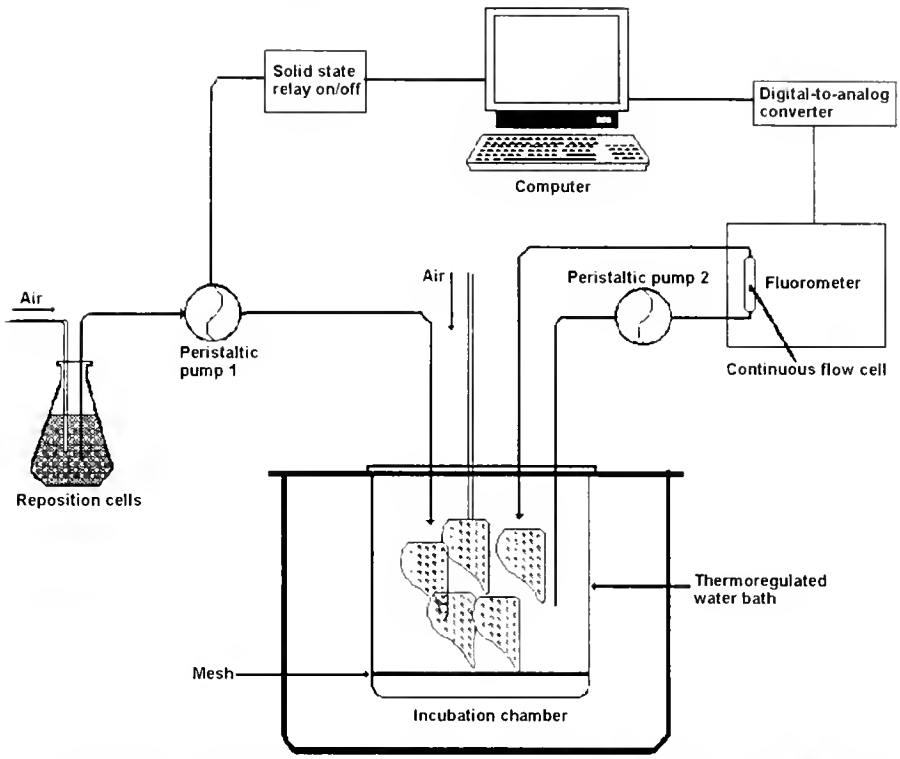

Figure 1. Apparatus employed for measuring clearance and ingestion rates in juvenile penshells (*Atrina maura*). Modified from Sicard et al. (1999).

where S was the concentration of microalgae in the replenishing stock.

From this, CR (Liters of water/g DTW/h) was calculated with the equation

$$CR = \frac{IR \times \text{Incubation chamber volume (L)}}{\text{Algal concentration in incubation chamber}}$$

The experiments were run in triplicate at each experimental temperature. An ANOVA was done to find significant differences of IR and CR at different temperatures. A Tukey's test was applied to find similarities among temperature treatments.

Growth and Survival

Growth and survival of penshell juveniles were recorded for 42 days. Groups of eight animals (18.7–21.0 mm shell height) were placed in tanks containing 19-L aerated seawater, 38‰ salinity and at the same experimental temperatures as in the previous experiments. The animals were fed $1.8 \pm 0.6 \times 10^8$ cells/individual/day of a mixture of *I. galbana* and *C. gracilis* at equal proportions. Half of the water was changed every day. Shell height was measured with plastic calipers every seven days over 42 days. Survival was measured daily, removing the dead animals from the tanks to avoid contamination of the water.

RESULTS

Dry Tissue Weight

The relation between dry tissue weight (DTW) and shell height (SH) of penshell juveniles is shown in Figure 2 and is described by the equation ($r = 0.95$; $n = 24$)

$$DTW = 2.3 \times 10^{-6} \times SH^{3.5}$$

Halotolerance

LD_{50}-96 of penshell juveniles to salinity is shown in Figure 3. Results show that the penshell withstands a range of salinity from 16.5‰ to more than the highest salinity tested (50‰) in the present study. As 85% mortality was only obtained at 50‰ salinity at 96 h, the median lethal time was calculated instead, extending the experiment until half of the population died at this salinity. Results indicate that the median lethal time for penshell juveniles was at 168 h (7 days) at this salinity (Fig. 3).

Thermotolerance

The upper temperature LD_{50}-96 of penshell juveniles is shown in Figure 4. Results indicate that *A. maura* tolerates high tempera-

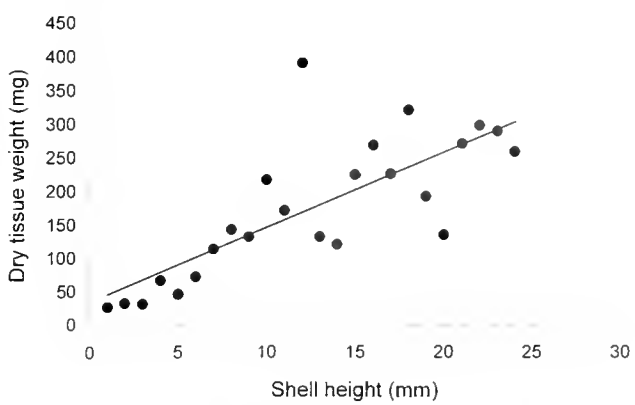

Figure 2. Relation between shell height and dry tissue weight in juvenile penshells (*Atrina maura*).

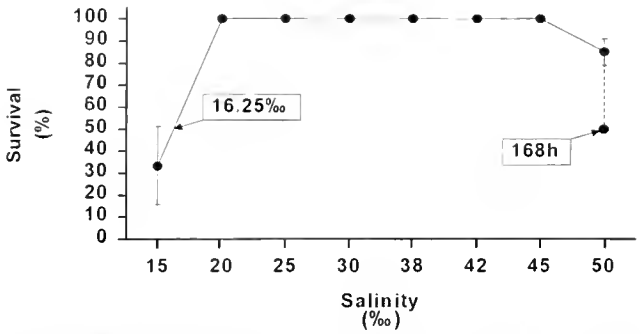

Figure 3. Median lethal dose at 96 h (LD_{50}-96) of salinity, on penshell (*Atrina maura*) juveniles. Because LD_{50} was not obtained at 96 h and at the highest salinity tested (50‰), the median lethal time was determined (broken line). Bars are the standard deviation of the means. $n = 3$.

tures, with the LD_{50}-96 of 33.2°C. Survival was not affected between 19 and 30°C, and at 32°C only 10% mortality was recorded.

Scope for Activity

Active (AR) and standard (SR) respiration rates at 16, 19, 25, and 29°C are shown in Figure 5. Results indicate that AR rates varied directly with temperature from 0.65 $mLO_2/g/h$ at 16°C, to 1.15 $mLO_2/g/h$ at 29°C. However SR rates remained stable between 0.2 and 0.4 $mLO_2/g/h$ and independent of temperature. SR was reached within 15 and 20 days from starvation in all treatments. With these results, the scope for activity (AR to SR) (Fig. 6) increased with temperature from 0.4 $mLO_2/g/h$ at 16°C to 0.9 $mLO_2/g/h$ at 29°C. The ANOVA indicated significant differences between temperature treatments at $P > 0.05$. However the Tukey's test revealed significant differences between all treatments but not between 16 and 19°C. No inflection of the curve was observed even at higher temperatures tested, which did not allow the determination of the temperature optimum in this species.

Ingestion and Clearance Rates

IR and CR of penshell juveniles are shown in Figures 7a and 7b. Results indicate that both rates increased with temperature, in the same manner as the scope for activity. Mean IR increased from 2×10^7 cells/g/h at 16°C, to 6.5×10^7 cells/g/h at 29°C. CR varied from a mean of 0.6 L/g/h at 16°C, to 2.25 L/g/h at 29°C. Large variations of IR and CR were observed between replicates of the all treatments, as indicated by the large standard deviation bars in

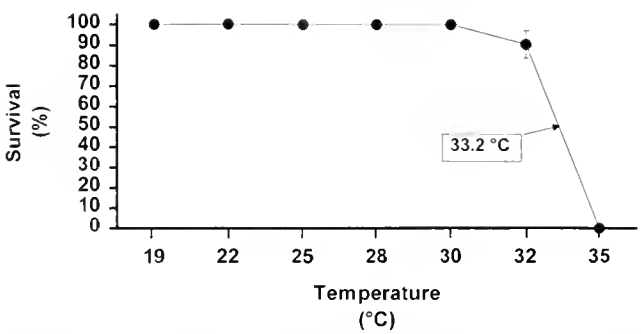

Figure 4. Upper median lethal dose at 96 h of temperature on penshell (*Atrina maura*) juveniles. Bars are the standard deviation of the means. $n = 3$.

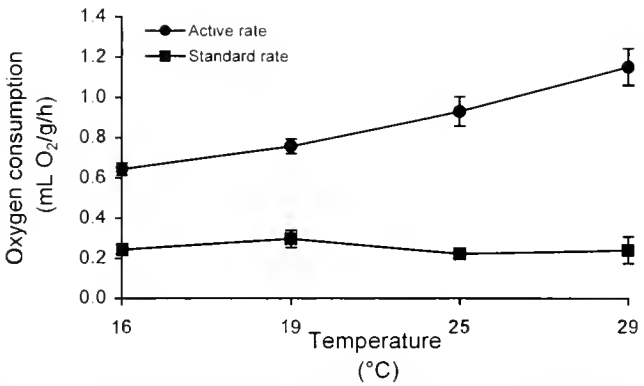

Figure 5. Active and standard respiration rates of penshell (*Atrina maura*) at different temperatures. Bars are the standard deviation of the means. $n = 3$.

Figures 7a and 7b. ANOVA indicated no significant differences of IR and CR at different temperature treatments ($P > 0.05$).

Growth and Survival

The results of growth experiments at 16, 19, 25, and 29°C are shown in Figure 8. Results indicate that growth in penshell juveniles correlated with temperature. Linear shell height increments of 0.021, 0.029 and 0.058 mm/day were obtained at 16, 19, and 25°C. However at 29°C, the height increment was low (0.5 mm) during the first 14 days, and then increased rapidly to 2.9 mm in 42 days. No explanation for this finding was found. Mortality was not recorded during the 42 days of experimentation in all treatments, with the exception of a slight decrease in survival (15%) on day 21 at 29°C.

DISCUSSION

The results indicate that *A. maura* is a tropical species that withstands a large range of salinity and high upper temperatures. Because of this, *A. maura* appears to be suitable for aquaculture in a wide variety of environments from hypersaline lagoons like those in Baja California, estuaries located along the Pacific coast of Mexico, Central, and South America, and probably in earthen ponds similar to those used in shrimp aquaculture. With our findings, temperature does not seem to impose a limit in the selection of sites, because the upper thermotolerance of penshells is greater than the maximum temperatures recorded in most bays of the Pacific coast of Mexico and of the Gulf of California (Lluch-Cota et al. 2000). In the present work, optimum temperature for growth

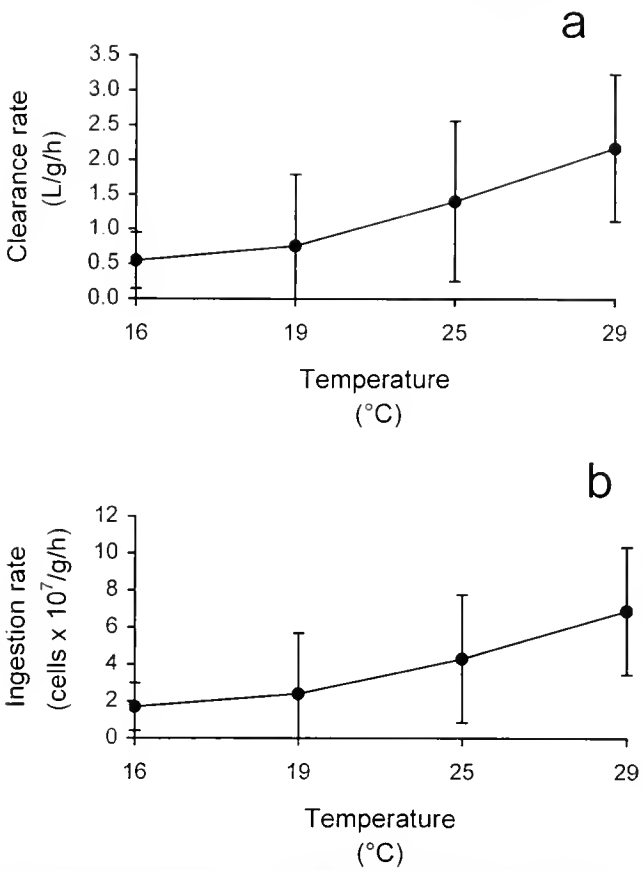

Figure 7. Clearance (a) and ingestion (b) rates of penshell (*Atrina maura*) juveniles at different temperatures. Bars are the standard deviation of the means. $n = 3$.

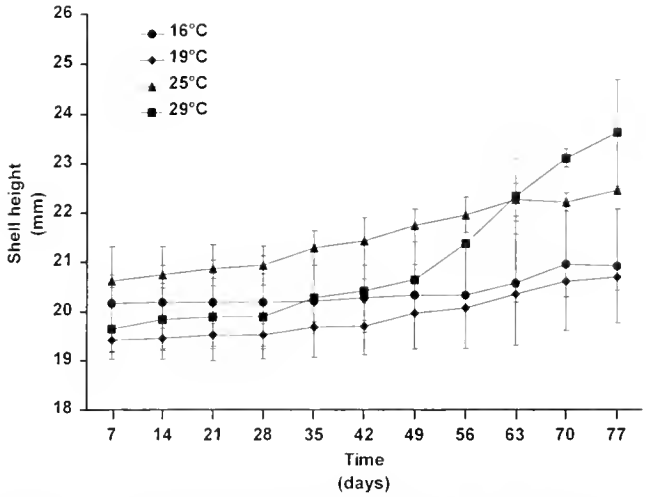

Figure 8. Growth of penshell (*Atrina maura*) juveniles, cultured at different temperatures, 38‰, and fed $1.8 \pm 0.6 \times 10^8$ cells/individual/day of a mixture of *Isochrysis galbana* and *Chaetoceros gracilis* at equal proportions. Values are the mean of 8 individuals ± standard deviation.

in penshell juveniles was not found within the range of temperatures studied. This could probably have been found if a higher temperature was tested. However, optimum temperature in *A. maura* is close to 29°C, because apart from the higher growth rate measured, reproductive maturation in the laboratory is faster at 25 and 30°C than at lower temperatures (Rodriguez-Jaramillo et al. 2001). Scope for activity and feeding rates gave identical results and coincided with growth experiments. This confirms the findings of previous work in catarina scallop (*Argopecten ventricosus*) (Sicard et al. 1999) where scope for activity, IR, CR, and growth gave similar results indicating an optimum temperature for growth of 19–22°C, in the range of temperatures tested (12–28°C). Therefore, any of the methods studied here appears to be adequate for the determination of optimum temperatures in molluskan species. However precision of feeding rates is lower than scope for activity and growth rates. Our ingestion and clearance rates experiments showed large variations between replicates of the same treatment. Variations do not seem to result from technical problems, but from a discontinuous feeding behavior of the animals. Large dispersion of IR and CR data have also been reported in *Argopecten irradians* (Kirby-Smith 1970), *Mytilus edulis* (Widdows and Bayne 1971) and in *A. ventricosus* (Sicard et al. 1999).

In contrast, Thompson and Bayne (1972), Bayne (1973), Bayne et al. (1973), Widdows (1973), and Sicard et al. (1999) have considered the scope for activity as a practical way to find the environmental conditions at which the energy available to the organism for growth and for other vital functions is a maximum. Both active and standard respiration rates are normally dependent on temperature as seen in *M. edulis* (Bayne 1976) and *A. ventricosus* (Sicard et al. 1999). However in our work, only the active rate varied with temperature. Standard respiration rate remained fully independent of temperature, which is not common. This is only found when insensitivity to temperature change may help to conserve metabolic energy reserves (Bayne 1976), as in situations of environmental stress (extremes of temperature, during starvation, or when exposed to air at low tide). Further work is needed to clarify these findings.

In the present work, salinity and upper temperature tolerance limits of penshell juveniles have been determined. We have demonstrated that the optimum temperature for growth in this species is 29°C or higher, making *A. maura* a good candidate for aquaculture in subtropical and tropical waters.

ABSTRACT We have developed an *in vitro* assay named Paralytic Shellfish Poison-test (PSP-test) that is capable of detecting low quantities of saxitoxin (STX), the first toxin studied from PSP. The PSP-test is an immunoassay based on the development of specific monoclonal antibodies (MAbs) capable of recognizing soluble saxitoxin (STX) and able to agglutinate in minutes, a latex containing STX adsorbed to its surface. The PSP-test is a two-step indirect immunoassay. During the first step, the MAbs are incubated with an extract suspected of containing STX. If the solution contains STX, this molecule will occupy the MAbs binding sites and block the latex agglutination. In the second step, MAbs-STX are incubated with an STX-latex. An inhibition indicates the presence of STX (PSP) in the sample. The PSP-test can detect within the range of 1.25–2.5 μg/ml of STX standard. It is also capable of recognizing STX in whole shellfish extract, acidic shellfish extract, and supernatants from aged toxic cultures of bacteria or dinoflagellates. The assay is simple, economic, and quick. Training of in its use is fast and harmless to the user. It can be performed in the field as a first screening procedure because an instrument to interpret the results is not required. However, the PSP-test was not developed to replace the mouse bioassay but rather to be complementary, and the strategy used for its development can be easily adapted to other toxins.

KEY WORDS: Paralytic shellfish poison, saxitoxin, monoclonal antibodies, dinoflagellates, assay

INTRODUCTION

The world oceans are affected by temporary massive proliferation of microalgae called Harmful Algal Blooms (HAB), commonly known as "Red Tides." Among the toxins produced by these HABs, the most feared is the Paralytic Shellfish Poison (PSP), a neurotoxic toxin produced by dinoflagellates like *Alexandrium, Gymnodinium* and *Pyrodinium*. There have been reports that some bacteria like *Anabaena, Aphanizomenos, Moraxella* and *Pseudomonas* are capable of producing PSP (Rausch and Lassu 1991).

Monitoring PSP toxicity potential in shellfish is carried out using the mouse bioassay, the only international assay accepted for certification of shellfish safety (AOAC 1990). The mouse bioassay has a detection limit of about 40 μg of STX for 100 g of total shellfish tissue. However, reports indicate that this assay has high variability (Park et al. 1986) and the maximum concentration of STX accepted for shellfish commercialization (80 μg/100 g) is too close to the limit of the mouse detection assay. This situation has stimulated the development of new methods for detection of toxin concentrations lower than those detected by the mouse bioassay. Among the new assays is high pressure liquid chromatography (HPLC) which is one of the most versatile and sensitive (Sullivan et al. 1983., Oshima et al. 1984). The fact that STX is able to block the activity of the voltage-dependent sodium channel and displace radioactive STX bound to brain membranes by cold STX present in the shellfish extract, allows quantification of the STX (Davio and Fontelo 1984). Other methods also include the cytopathic effect of STX on neuroblastoma cells cultures (Kogure et al. 1988) and the use of monoclonal and polyclonal antibodies in several immunoassays formats (Chu and Fan 1985; Carlson et al. 1984; Davio, et al. 1985 and Usleber et al. 1991). The most accurate and reliable assay to detect PSP is liquid chromatography followed by mass spectrometric analysis, LC-MS (Quilliam et al. 1993). The main advantage of the assays listed above is, that they allow the evaluation of several shellfish samples simultaneously within a relatively short period of time when compared to the mouse bioassay. However, these assays can be performed only under laboratory conditions requiring expensive infrastructure and most of them cannot be easily adapted to field conditions as required to perform daily monitoring. Furthermore, the mouse bioassay is a time consuming and an expensive procedure. The main reason to maintain the mouse bioassay is that it detects the whole shellfish toxicity regardless of which toxin or toxin-complexes are present in the shellfish sample. On the other hand, animal rights defendants groups are encouraging and pressing the scientific community to look for alternative assays that will allow the elimination of the mouse bioassay or at least reduce the number of animals used.

Here, we describe an indirect immunoassay that detects low quantities of STX from a single shellfish sample. PSP-test is a qualitative assay, economical, easily adaptable to other toxins or toxic profile, and does not require instruments to interpret the results. Thus, the PSP-test can be adapted to field conditions allowing to rapidly alert shellfish farmers of the presence of contaminated shellfish and can be used as primary screening of samples before analysis of mouse bioassay.

MATERIALS AND METHODS

Generation of Monoclonal Antibodies (MAb)

STX was purchased from Sigma Chemical Company (St, Louis, MO). It was bound to hemocyanin ("blue carrier" protein), Biosonda (Santiago, Chile) to be used as immunogen and to bovine serum albumin (BSA) to be used as antigen for screening as described elsewhere by Levine et al. (1988)). Briefly, STX's hydroxyl group was modified using CMA (carboxymethylamine). It was then, incubated with a water-soluble carbodiimide EDC, followed by incubation for 1 h at room temperature with blue carrier

*Corresponding author. E-mail: jcordova@bionova.cl; Fax: +56-2-239-4250.

protein. The ration STX-Protein was 100:1. Free STX was separated from the STX-protein conjugate by centrifugation through a microconcentrator Centricon™ 30 tube (Amicon, Danvers, MA). Similarly, STX was adsorbed to 1 μm latex following manufactures indications, Bangs Labs. (Fishers, IN). To immunize the animals, 50 μg of STX-blue carrier conjugate was mixed with Complete Freund Adjuvant, Gibco (Grand Island, NY) just before immunization. Female 10-week-old BALB/c mice were immunized subcutaneously. After the first immunization, four additional boosts were done at 20-day intervals. Five days after the last boost, serum samples were drawn from each mouse and their titers were determined by ELISA using polystyrene plates DK 4000, Nunc (Roskilde, Denmark) coated with the STX-BSA as antigen as described elsewhere by Chu (1985). The mouse with the highest titer for STX-BSA was used to generate the monoclonal antibodies.

After immunization, spleen cells from the selected mouse were fused with 2.5×10^7 NSO/2 mouse myeloma cells using 50% polyethylene glycol 4000 Merck (Rahway, NJ) as described by Köhler and Milstein (1975). Then, the cells were suspended in Dulbecco supplemented with 1% nonessential amino acids, 10% fetal bovine serum (FBS), HyClone Labs. (Logan, UT), penicillin (100 IU/ml), streptomycin (100 μg/ml), 2 mM L-glutamine, 10^{-2} M hypoxanthine, 4×10^{-5} M aminopterin, and 1.6 μ 10^{-3} M thymidine, HAT selecting medium, Sigma, (St. Louis, MO). Aliquots of 100 μl were plated on 96-well tissue culture plates. The plates were incubated at 37°C in a moisturized atmosphere with 10% CO_2 in the air. ELISA, as described previously, screened 10 days after fusion, supernatants from cultures with hybridoma growth for specific monoclonal antibody secretion. All positive cultures were expanded onto 24-well plates, and cell samples were frozen in liquid nitrogen in a medium containing 90% FBS and 10% dimethylsulfoxide. Positive clones were re-cloned by limited dilution. Three hybridomas (8C3/A7, 6A4/H7 and 3F7) were selected for the test.

Shellfish Sample Extracts

Two types of shellfish samples were utilized for evaluation using the PSP-test. One, freshly frozen untreated shellfish from Aysén, XI region of Chile (43°45′ to 48°45′, Fig. 2 and Table 2). These same shellfish samples were subjected to acid extraction in performing the mouse bioassay (AOAC 1990). The other type was acidic shellfish extracts previously used to perform the mouse bioassay, obtained from different Chilean geographic areas affected by PSP.

Dinoflagellate Cultures

The OF875-17 clone of *A. tamarense* from Ofunato, Japan and clone GTCA28 of *A. fundyense* from New Hampshire, USA were

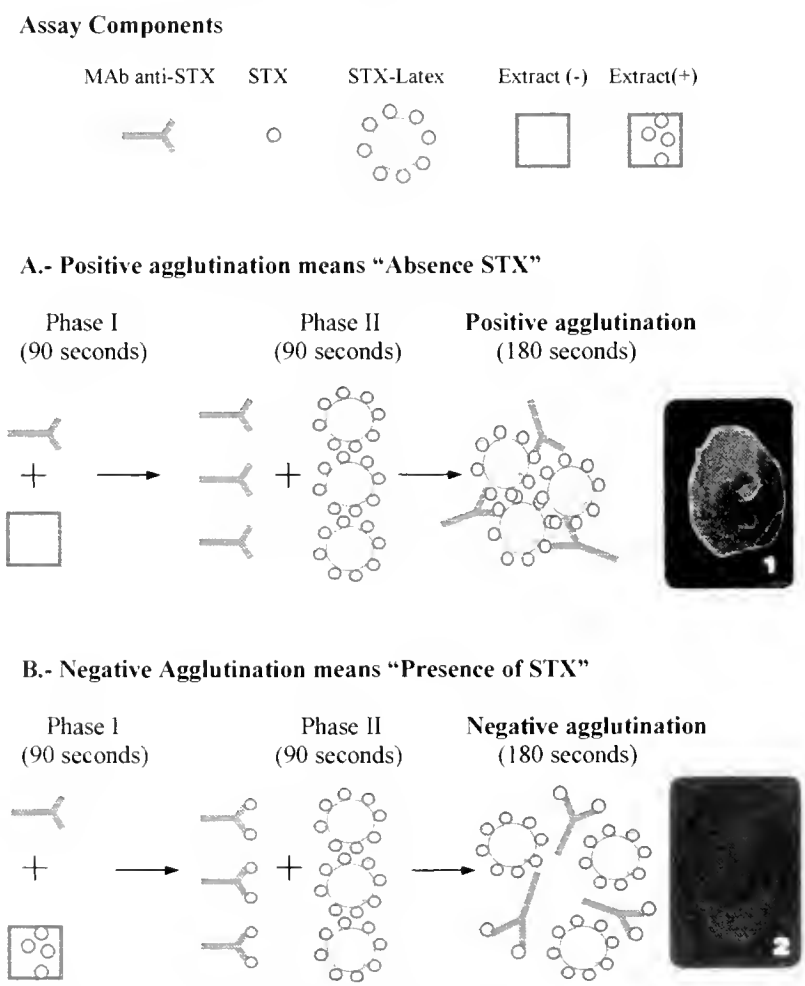

Figure 1. PSP-test assay detection principle. The latex agglutination indicates the absence of STX in the sample (A), while the inhibition indicates STX in the sample.

TABLE 1.

Assay detection limit and recognition of STX-isomers.

A Toxin	Concentrations				
Saxitoxin standard (μg/ml)	10	5	2.5	1.25	0.625
Agglutination	No	No	No	Yes	Yes

B Toxin	Concentration	Detection limit
Neosaxitoxin	28 μg/ampule	25 μg/1 mL
$GTX_{1/4}$ – 1	14.8/6.4 μg/ampule	39 μg/1 mL
$GTX_{2/3}$ – 1	24.8/5.8 μg/ampule	36 μg/1 mL
GTX_5 or B1*	~100 μg/ampule	200 μg/1 mL

Oligoclonal anti-STX antibodies cross-reactivity was assessed using commercially available STX and its isoforms. The lower STX concentration that induces inhibition of the agglutination was 1.7 μg/ml (A) and for the isoforms are as indicated (B).

kindly donated by Dr. Donald M. Anderson, Biology Dept., Woods Hole Oceanographic Institution, MA, USA. The ACC07 clone of *A. catenella* was isolated on April 1994 from Costa Channel, XI region, Chile (45°32′S, 73°34′W), and was kindly donated by MSc. Miriam Seguel, IFOP, Puerto Montt, Chile. Dinoflagellate cultures were maintained in glass tubes at 10°C with constant light until they reached stationary phase. Culture media consisted of sea water sterilized by passage through 0.2 μm filtration units Nalgene (Rochester, NY), supplemented with Guillard f/2 marine enrichment basal salts and vitamins (Sigma), as described by Guillard, (1975).

Bacterial Cultures

Pseudomonas diminuta was isolated from the ACC07 clone of *A. catenella*. The *Moraxella sp.* strain was isolated from *A. tamarense* and kindly provided by Dr. Masaki Kodama, School of Fisheries Sciences, Kitasato University Sanriku, Iwate, Japan. Free-living bacteria identified as *Pseudomonas versicularis* and *Proteus vulgaris* were isolated from the Magellan Strait, Chile. All bacterial strains were grown in Zobell marine media and kept at 10°C (Kodama et al. 1988).

PSP-Test Assay Procedures

Determination of the Assay Detection Limit

Ten microliters of a 1:30 dilution of the oligoclonal anti-STX (a mixture of three MAbs that recognize STX) was mixed with 10 μl of? a serial dilution of STX standard in distilled water (Sigma) and placed over a spot in the agglutination plate, mixing for 90 seconds at room temperature. Then, 10 μl of STX-latex was added and mixed by gentle swirling of the agglutination plate until agglutination was visible in the control (without free STX). Also, the anti-STX cross-reactivity of the oligoclonal antibody mixture to STX-isoforms, neosaxitoxina (Neo-1), gonyautoxins-1 (GTX1/4-1), gonyautoxins-2 (GTX 2/3-1), and gonyautoxin-5 acetate (GTX-5 or B1), all obtained from the Certified Reference Materials Program, Institute for Marine Biosciences, National Research Council of Canada, were evaluated.

Evaluation of the Presence of STX in Freshly Frozen Shellfish

Samples were allowed to thaw at room temperature. Approximately 0.1 g of digestive individual gland was mixed in an Eppendorf tube with 100 μl of distilled water and minced with a pestle until the suspension was homogeneous. The tubes were then centrifuged at 14,000 rpm for 3 min (Eppendorf, Nathalar, Germany) and 10 μl of the supernatant was placed on the agglutination slide and evaluated, as described previously. Agglutination occurs in the control spot about five minutes after the initiated reaction. The reaction for each sample was evaluated and scored as positive or negative for agglutination.

Evaluation of Whole Acidic Shellfish Extracts

Extracts from toxic and non toxic shellfish were obtained according to the AOAC procedure (AOAC 1990). Ten microliters of each sample was placed on the agglutination slide without neutralization and evaluated, as described previously.

Evaluation of Supernatants from Toxic Organisms

One milliliter of culture from stationary phase (10–12 days) either bacteria or dinoflagellate, was individually placed in an Eppendorf tube, after a quick spin to pellet the cells, 10 μl of supernatant was placed on the agglutination slide and evaluated, as described previously.

RESULTS

Assay Rationale

A mixture of MAbs (oligoclonal) generated against STX recognizes STX present in the latex surface (STX-latex) and agglu-

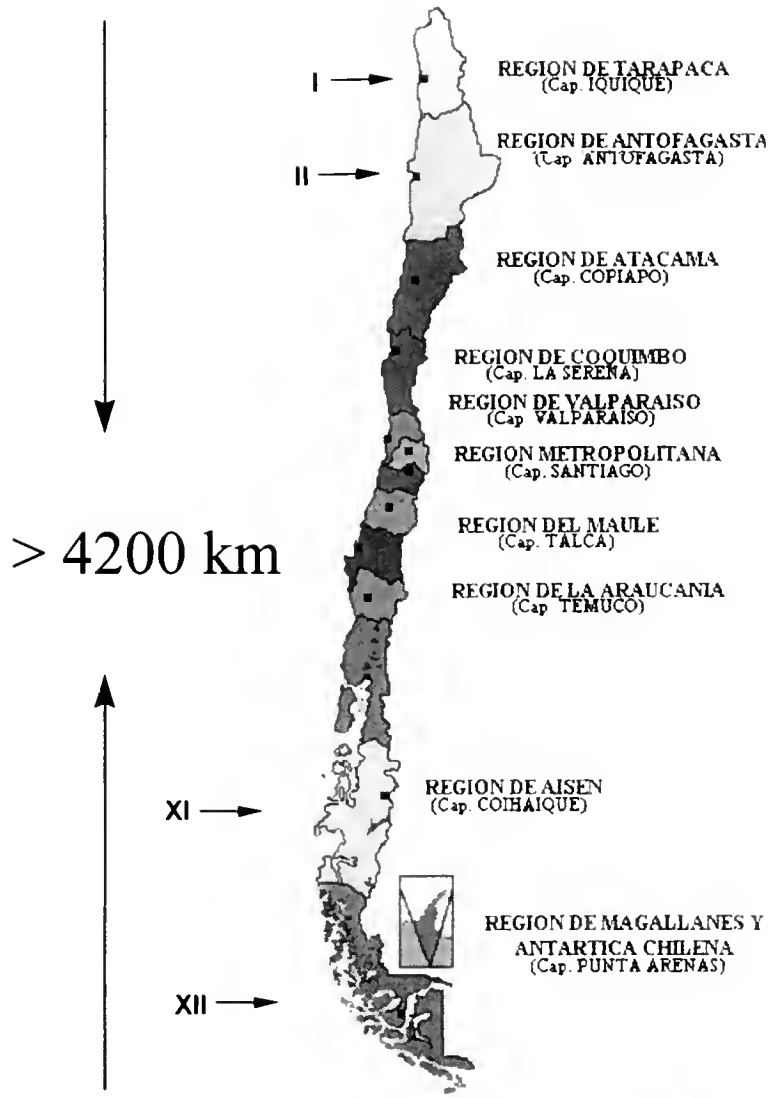

Figure 2. Geographical origin of Chilean shellfish samples used in this paper (Regions I, II, XI, and XII).

tinates it. The MAbs should not agglutinate the STX-latex if their binding sites are occupied by STX present in the sample (Fig. 1). Thus, if a sample, that does not contain STX, is mixed with the anti-STX MAbs, their binding sites will remain free and able to agglutinate the STX-latex. This positive agglutination indicates the absence of STX (PSP) in the sample. However, if the sample does contains STX, then the MAbs binding sites will be occupied and would not be able to agglutinate the STX-latex. Thus, the lack of agglutination indicates the presence of STX (PSP) in the sample.

Assay Detection Limit and Recognition of STX-Isomers

The detection limit was established as the minimal concentration of standard STX that inhibits agglutination after five minutes of reaction at room temperature. For STX this limit was in the range of 1.25–2.5 μg/ml (Table 1A). However, additional experiments with different STX sources indicate that this minimal inhibitory concentration may vary according to the sample condition, i.e. acid shellfish extract, culture, fresh, or canned (data not shown).

The PSP-test was evaluated to determine whether the MAbs recognize STX-isoforms. The MAbs anti-STX recognize different STX-isoforms evaluated as indicated in Table 1B. The STX-isoforms concentration that inhibits the agglutination is greater, as expected, compared to that of STX from monoclonal antibodies raised and screened for that purpose.

Analysis of Fresh Frozen Samples

Once the PSP-test assay conditions were established, we were interested in determining whether the assay can detect PSP in individual non-chemical extracts from freshly frozen samples. The results are presented in Table 2. Also, the same samples were used to detect PSP using the mouse bioassay with 3 mice of the F-1 strain. Death times and PSP concentration calculations are included in Table 2.

Table 2 shows the results of the analysis done on 20 samples of 4 different shellfish species obtained from eight different places of XI region (Fig. 2). These frozen samples were all from one individual organism and stored under non-standardized conditions to

reflect field conditions more closely. Results obtained with the mouse bioassay and with the PSP-test are compared in Table 2. The analysis shows that the mouse bioassay detected 17 (85%) positives out of 20 samples, and when the same shellfish samples were evaluated, the PSP-test detected 15 positives out of 20 (75%).

Analysis of Whole Acidic Shellfish Extracts

Whole acidic shellfish extracts from four different Chilean regions (Fig. 2) including eight different shellfish species from different years, were evaluated for PSP with the mouse bioassay, the data obtained are presented in Table 3. The same samples were evaluated with the PSP-test, giving a 100% of positive correlation with the mouse bioassay. Twenty-five samples of whole acidic shellfish extracts from non toxic shellfish (as determined by the mouse bioassay) gave negative results with the PSP-test assay (data not shown).

Analysis of Dinoflagellates and Bacterial Cultures

To determine whether the PSP-test assay could be used to detect toxic dinoflagellates reported as primary sources of PSP, we carried out the PSP-test in culture supernatants as well as in their supernatants obtained after cell homogenization. The results are shown in Table 4A. They indicate that the PSP-test detects PSP in both samples, regardless of which *Alexandrium* species we tested or where they came from.

In addition, the PSP test was shown as being capable of detecting toxins on culture supernatants from *P. diminuta*, a bacterium isolated from a Chilean strain of *A. catenella*, (Córdova et al., 2000). As positive control, we used a supernatant from cultures of *Moraxella sp.* a bacterium isolated from *A. tamarense* (Kodama et al. 1988). The confirmation that the bacteria isolated produced STX was done by HPLC (data not shown). Finally, several free-living marine bacteria isolated from XII region, Chile, were also evaluated for PSP production using the PSP-test. The results indicate that only two isolates, *P. versicularis* and *P. vulgaris*, were capable of producing PSP.

DISCUSSION

The mouse bioassay is used to monitor shellfish toxicity for legislative purposes (open or closing areas for shellfish harvesting), as well as to evaluate shellfish wholeness, fresh or canned, before commercialization and human consumption. Thus, evaluation of shellfish toxicity has been the best alternative to mitigate the negative impact of PSP poison in the community.

Despite the effectiveness over the years of the mouse bioassay in detecting shellfish toxicity, there are problems with accuracy

Bacterial and dinoflagellate cell cultures were evaluated detecting toxic dinoflagellate in their culture supernatant from stationary phase, as well as in their supernatants from cell homogenization (A).

Isolated bacteria from toxic dinoflagellate (1 and 2) as well as free living bacteria from the XII region of Chile (8 and 9) were detected positive for PSP production (B).

Other intracellular as well as extracellular bacteria tested negative for PSP production.

* PSP positive *Moraxella* sp. from Dr. Kodama.

and poor reproducibility when shellfish is contaminated with low concentrations of PSP. This indicates that there is a need for quick, sensitive, and economic assay, complementary to the mouse bioassay. The PSP-test could also be used for fast screening of toxic shellfish, allowing better management, hopefully, just before shellfish harvesting or to monitor toxic shellfish that undergo detoxification procedures, or shellfish acidic extracts before mouse bioassay, thereby reducing the number of mice used.

The PSP-test assay reported here has proven to be effective in detecting PSP in freshly frozen shellfish species, 15/20 (75%) when compared with positive samples in the mouse bioassay 17/20, (85%). The negative PSP-test results could indicate the presence of new STX isomers in the sample, different from those evaluated in Table 1B, which are not recognized by the MAbs anti-STX. However, this hypothesis, although possible, is unlikely because the death-times of the mice suggest high toxin concentration. Another explanation for this result could be that the shellfish among those pooled were diverse and possibly, not all contaminated, thereby resulting in different amounts of toxins in an individual assay. The mouse bioassay uses extracts from 100 g of shellfish; approximately 12 to 15 types of shellfish, increasing the chances of detecting toxicity. However, PSP-test uses an individual sample and a low amount of tissue. Finally, the possibility exists, although minimal, that some deaths might be due to a toxin that resembles PSP and consequently there would be no detection with PSP-tests. Unfortunately, samples to perform such, as HPLC or liquid chromatography-mass spectrometry, were not considered because we have no access to these technologies.

When the PSP-test was used in evaluating positive acidic shellfish extracts that were positive to the mouse bioassay, the results indicated 100% positive correlation. Therefore, based on this result, the PSP-test detects PSP under acidic conditions, suggesting that there is a potential for it to be used as a primary screening assay for these types of samples. Perhaps the number of mice used to evaluate PSP in shellfish acid extracts could be reduced. We believe that 100% correlation was obtained because toxins are concentrated from 100 g of shellfish. Regardless of what type of STX isoforms were present in the samples, under this acidic condition, they tend to transform to STX, isoform that is detected by PSP-test. The versatility of the PSP-test was also demonstrated when toxic cultures of dinoflagellates and bacteria were detected. However, a significantly higher number of samples will be necessary to assess the full potential of the PSP-test to detect PSP from different sources.

It is important to note that the PSP-test assay was not developed with the intent to replace the mouse bioassay, because it is incapable of recognizing "whole shellfish toxicity" as detected by the mouse (Table 2), which can be due to the highest standardization and reproducibility of sample preparation. However, the PSP-test has proven useful for detection of lower concentrations of PSP in fresh frozen shellfish, which indicates its potential use in testing field samples and for different shellfish species. The most important Chilean shellfish for local human consumption and for export were evaluated using the PSP-test. The following: "almeja del norte", *Prothaca thaca*; "almeja del sur", *Venus antiqua*; "chorito", *Mytilus chilensis*; "cholga", *Aulacomya ater*; "culengue", *Gari solida*; "loco", *Concholepas concholepas*; "macha", *Mesodesma donasium*; "ostión del norte", *Chlamys (Argopecten) purpuratus*; "picoroco", *Megabalanus psittacus*; indicates 9 out of these 19 species (47%) used. Moreover, the PSP-test can be improved by developing new MAbs characteristics to specific STX isomers present in the PSP, adapting it to different conditions and toxin profiles. Finally, the PSP-test uses a new technology that can be easily adapted for other shellfish toxins, and because it is economical and quick has the potential for uncomplicated shellfish monitoring.

ACKNOWLEDGMENTS

We thank the members of Programas sobre el Ambiente del Servicio de Salud de Aysén for the shellfish samples. Thanks are also due to Mr. Alvaro Morales for taking care of the immunized animals. This work has been supported by the Organization for the Prohibition of Chemical Weapons, The P. Valenzuela & B. Méndez Foundation, FONDECYT Project 1970808. The Millennium Institute for Fundamental and Applied Biology is financed in part by MIDEPLAN (Chile).

SPECIFIC INHIBITION OF ENDOGENOUS SHELLFISH PROTEIN PHOSPHATASE THAT COULD BE USED AS A DIRECT REPORTER OF DIARRHETIC SHELLFISH POISON

JOSÉ LUIS CÓRDOVA,* JUANA BUSTAMANTE, AND LEONIDAS CÁRDENAS

Fundación Ciencia para la Vida and Millennium Institute for Fundamental and Applied Biology, Av. Marathón 1943, Ñuñoa, Santiago, Chile

ABSTRACT Diarrhetic Shellfish Poisoning (DSP) is a human gastrointestinal disorder associated with the consumption of contaminated shellfish. Okadaic acid (OA) and dinophysistoxin-1 (DTX-1) are diarrogenic DSP toxins, which also have tumor promotion and protein phosphatase inhibition activities. It is also known that OA and DTX-1 toxins localize mainly in the shellfish digestive gland; although, it remains to be explained how the toxins are retained in this tissue. Total protein of shellfish digestive gland from different shellfish species was fractionated using gel electrophoresis under nondenaturing conditions followed by specific phosphatase colored reaction. This procedure allows the identification of endogenous shellfish protein phosphatases that are shellfish species specific. Moreover, when shellfish digestive glands naturally contaminated by DSP were evaluated using the same procedure, one or both of previously identified endogenous protein phosphatase activities showed reduction or inhibition as compared to uncontaminated controls. To demonstrate experimentally that the protein phosphatase inhibiton observed were attributable to DSP toxins, shellfish of *Venus antiqua* were toxified using *Prorocentrum lima* cells under laboratory conditions, and their digestive glands were analyzed as described above. The same protein phosphatase inhibition was detected in shellfish naturally contaminated with DSP. These observations suggest that endogenous shellfish protein phosphatases could act as acceptors for DSP toxins, and their analysis can be used as a simple and sensitive assay to detect DSP toxins in shellfish, avoiding DSP purification steps, and reducing the time for DSP detection and animal use.

KEY WORDS: diarrhetic shellfish poison (DSP) detection, shellfish acceptors for DSP toxins, endogenous shellfish protein phosphatase detection, DSP monitoring

INTRODUCTION

Dinophysis sp. and *Prorocentrum* sp. are marine dinoflagellates that produce toxins that cause diarrhetic shellfish poisoning (DSP) in humans after consumption of contaminated shellfish. Yasumoto et al. (1979) was the first to describe this syndrome in which *Dinophysis fortii* was identified as the biological source for DSP toxins found in contaminated shellfish in Japan (Yasumoto et al. 1980). Since its discovery in Japan, DSP syndrome has been reported in other countries worldwide (Maestrini, 1998).

Among the DSP toxins, okadiac acid (OA) and dinophysistoxin-1 (DTX-1) can cause diarrhea, and both also are tumor promoting agents and inhibitors of protein phosphatases (Yasumoto et al. 1985, Takai et al. 1987, Fujiki et al. 1988). Although most countries accept up to 200 ng of OA per g of tissue, there is a general consensus that only shellfish free of OA and DTX-1 for human consumption and international commercial trade should be acceptable.

Shellfish probably become contaminated by concentrating DSP toxins while feeding on marine phytoplankton (Murakami et al. 1982, Bauder et al. 1996, Quilliam et al. 1996). Moreover, several assays have been developed to detect smaller quantities of OA and DTX-1 in shellfish samples, especially because of their tumor-promoting activity. The assays to detect DSP toxins can be grouped into two sets. The first set includes assays that can detect such DSP biological activity as the mouse bioassay (Japanese Ministry of Health and Welfare 1981), effects on rat appetite (Terao et al. 1993), dehydration effects on the newborn mouse intestine (Hamano et al. 1986), and cytophatic effects on cultured cells (Amzil et al. 1992). In addition, a colorimetric assay was developed based on the ability of OA to inhibit phosphatases PP-1, PP-2A, and PP-2B (Shikari et al. 1985). The second set of assays detects DSP active molecules and their isoforms or intermediary molecules. These are enzyme-linked immunosorbent assay (ELISA) (Uda et al. 1989); radioimmunoassay (RIA) (Levine et al. 1988), high-power liquid chromatography (HPLC) (Lee et al. 1987), and the most sophisticated assay, liquid chromatography followed by a mass spectrometry (LC-MS/MS) (Pleasance et al. 1990). However, all of these assays require several steps of purification before they are performed. Clearly, a simpler and economical assay is needed to monitor DSP toxins in shellfish before harvesting and to reduce the number of mice used in the bioassay, because of its poor reproducibility, high number of false-positives, and the excessive time required to determine toxicity (Tagaki el al. 1984, Kogawa et al. 1988).

Here, we report that endogenous shellfish protein phosphatase activity localized in digestive glands can be easily identified using gel electrophoresis (SDS-PAGE) under nondenaturing condition followed by specific colored reaction. Using this procedure, it was possible to demonstrated that protein phosphatase activity from three different species of shellfish naturally contaminated with DSP are specifically disminished or inhibited, as compared to their uncontaminated control samples. Moreover, DTX-1 was detected by LC-MS when the gel band containing the inhibited protein phosphatase was analyzed. Furthermore, protein phosphatase inhibition similar to DSP natural contaminated shellfish, was observed when *Venus antiqua* was toxified with *Protocentrum lima* cells under laboratory conditions. Finally, protein phosphatase activity or its inhibition can be detected in as little as 100 μg of total protein from aqueous extract of digestive tissue gland without purification steps. These observations suggest that endogenous shellfish protein phosphatases localized in the digestive gland act as DSP aceptors. Furthermore, analysis of the endogenous shellfish protein phosphatase condition (active or inhibited), may be used as a simple and sensitive assay to detect DSP toxins in shellfish, avoiding DSP purification steps, reducing the time for DSP detection and animal use.

MATERIAL AND METHODS

Microalgae Cultures

The Canadian strain of toxic *Prorocentrum lima* was kindly provided by Dr. Allan Cembella (Institute for Marine Biosciences, National Research Council, Nova Scotia, Canada). Microalgae were cultured at 15°C in f/2 medium (Guillard 1975) and were exposed to continuos illumination provided by day-like type fluorescence light. Cultures of the nontoxic microalgae used to feed shellfish were: *Isochrysis galbana*, *Isochrysis suecica*, *Nannochloris* sp., and *Pavlova* sp. were kindly provided by Dr. Gloria Coyantes (Montemar, Valparaíso University, Chile) and maintained with the same conditions as for the *P. lima* culture. Three-week-old cultures of *P. lima* were used to toxify shellfish.

Evaluation of Endogenous Shellfish Protein Phosphatase Activity

Positive DSP frozen digestive glands of different shellfish species *Aulacomya atter*, *Mytilus chilensis*, and *Venus antiqua* were from the Chilean Monitoring Program and kindly donated by Ms. Georgina Lembeye. These samples were evaluated using the mouse bioassay (Yasumoto 1984, Japanese Ministry of Health and Welfare 1981), although exact concentration of DSP was not determined. Uncontaminated shellfish species of *A. atter*, *M. chilensis*, and *V. antiqua* for control were bought from a local seafood market. Frozen tissues were thawed on ice. Then, 0.1 g of each tissue was individually mixed with 200 μL of sterile distilled water, minced, and centrifuged at 14,000 rpm for 5 min using a benchtop centrifuge. Protein concentration was determined using the BioRad DC kit (Richmond, CA), and adjusted to 2 mg ml^{-1}. Fifty μL of the aqueous extract was mixed with 50 μL of SDS-PAGE sample buffer (0.0625 M Tris-HCl, pH 6.8; 10% glycerol, 2.3% sodium dodecyl sulfate (SDS), and 0.00125% of bromophenol blue). The sample was fractionated without heat denaturation using 8% sodium dodecyl sulfate-polyacrylamide gel (7.5 × 10 cm) electrophoresis (SDS-PAGE) according to Laemmli (1970) in a Mini Protean II Electrophoresis Cell (BioRad). The prestained molecular weight marker proteins were from New England BioLabs (Beverly, MA). The gel run at 60 V for 2 h using 0.025 M Tris-HCl pH 8.8; 0.192 M glycine, and 0.0035 M SDS as running buffer. The gel was then washed three times with distilled water for 5 min each at room temperature. Next, the gel was incubated with alkaline phosphatase buffer (100 mM Tris-HCl pH 9.5; 5 mM MgCl2; 100 mM NaCl) for 10 min at room temperature. The buffer was then replaced and supplemented with 4.3×10^{-4} M of 5-bromo-4-chloro-3-indolyl phosphate and 3.9×10^{-4} M of nitro blue tetrazolium (BCIP-NBT, Sigma Chemical, St. Louis, MO) dissolved in 100 and 70%, respectively of N,N-dimetylformamide (Merck, Darmstadt, Germany), and incubated at room temperature until precipitated bands were visualized. After the bands were clearly identified, the gel was washed twice with distilled water and scanned using the AGFA studioscan II Si connected to an Apple Macintosh Performa 5300 computer.

Detection of Protein Phosphatase Activity in Shellfish Contaminated Under Laboratory Conditions

Four live *V. antiqua* shellfish from a local seafood market were washed with fresh seawater and placed onto a 1-L beaker containing 600 mL of fresh seawater. The beaker was maintained at 10°C, and also air was bubbled constantly into it using a fish tank pump. Shellfish viability was confirmed when the shells opened, and water circulation was observed through the siphons. Shellfish were fed daily for seven days as follows: air bubbling was stopped; 2 mL containing of 10^5 cells ml^{-1} of a three-week-old *P. lima* culture were added to the beaker. Ten minutes later, 5 mL containing a mixture of 10^6 cells ml^{-1} of viable nontoxic microalgae *I. galbana*, *I. suecica*, *Nannochloris* sp., and *Pavlova* sp was added to each beaker. After 30 min, air bubbling was reinitiated. After the seventh day, digestive glands were individually removed from each group and individually analyzed by SDS-PAGE, as described above. The seawater was changed once during the seven-day experiment. These experiments were carried out with aged *P. lima* cultures, because it has been shown that older cultures are more toxic (Quilliam et al. 1996).

Analysis of the SDS-PAGE Band Containing the Inhibited Protein Phosphatase

Ten milligrams of protein aqueous extract from *V. antiqua* digestive gland DSP naturally contaminated were fractionated by SDS-PAGE (15 × 17 cm), as described above. The gel piece containing the inhibited protein phosphatase band (using as reference the prestained molecular weight markers) was cut off and subjected to three washes with distilled water. The gel piece was then minced and mixed with 5mL of 50% methanol, and vortexed for 10 min at room temperature. The gel fragments were then also subjected to constant sonication for 2 min using the lower power of a Sonifier 450 (Branson Ultrasonic, CT). The sample was centrifuged at 2,500 rpm for 10 min and the supernatant concentrated at 65°C until 1 mL of volume; it then was completely dried out using a speed-vac system. The sample was sent to Institute for Marine Biosciences, National Research Council of Canada, in Canada, for analysis by liquid chromatography-mass spectrometry (LC-MS) according to Pleasance et al. (1992) to determine which DSP toxin was present in the gel band.

RESULTS

Protein phosphatase activities from three different shellfish species were characterized by SDS-PAGE followed by phosphatase specific staining that produces a precipitated colored band (Fig. 1). Uncontaminated *A. atter* and *M. chilensis* had two bands at 85 and 150 kDa (Fig. 1, Lanes 1 and 3); *V. antiqua* has two bands at 70 and 140 kDa (Fig. 1, Lane 5). The two bands in *A. atter* and *M. chilensis* showed similar protein phosphatase activity as deduced from the intensity of their bands, which was optically assessed. In contrast, in *V. antiqua*, the higher band (140 kDa) had a greater protein phosphatase activity than the lower band (70 kDa).

On the other hand, shellfish naturally contaminated with DSP toxins had their protein phosphatase activities significantly inhibited (Fig. 1, Lanes 2, 4, and 6. Thus, for *A. atter* and *M. chilensis*, the inhibition was similar and inhibited preferentially the higher band in both species (Fig. 1, Lanes 2 and 4). In contrast, *V. antiqua* had a different inhibition pattern: the lower band was almost totally inhibited, while the higher band seemed to have the same or more activity with respect to control band (Fig. 1, Lane 6).

Furthermore, analysis of the methanolic extract corresponding to the 70 kDa protein band from DSP naturally contaminated shellfish using the LC-MS analysis demonstrated the presence of DTX-1 at approximately concentration of 2 ng ml^{-1} (data not shown).

To confirm that inhibition of the 70 kDA protein phosphatase

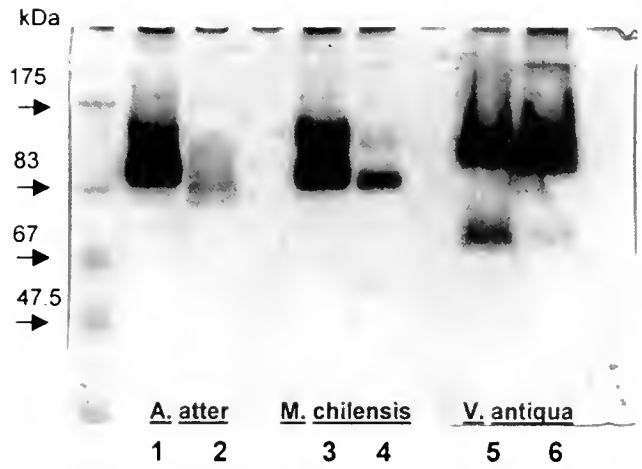

Figure 1. Shellfish phosphatase patterns. Phosphatase activities from three different shellfish species were determined by SDS-PAGE. Phosphatase activities from noncontaminated shellfish (Lanes 1, 3, and 5) are compared with shellfish naturally contaminated with DSP toxins (Lanes 2, 4, and 6). Molecular weight markers are as indicated.

band observed on naturally DSP-contaminated *V. antiqua* was attributable to DSP toxins, two groups of this shellfish were cultivated under laboratory conditions, only one group was fed with toxic *P. lima* cultures. The results are shown in Figure 2. Lanes 1 and 3 correspond to protein phosphatase activity of shellfish control that was fed only with nontoxic microalgae cultures. However, in this case, three protein phosphatase activity bands were visualized at 50, 70, and 140 kDa (Fig. 2, Lanes 1 and 3). Although in contaminated samples (Fig. 2, Lanes 2 and 4), the 140 kDa showed an increased protein phosphatase activity it when was compared to the same band in the noncontaminated shellfish. The 50 and 70 kDa bands were inhibited.

DISCUSSION

This work reports that endogenous shellfish protein phosphatases localized in digestive glands undergoes specific inhibition as result of contamination with DSP toxins. Protein phosphatase activity can be visualized after separating them from the shellfish digestive gland using SDS-PAGE nondenature condition and exposure to phosphatase-specific substrates that precipitated upon

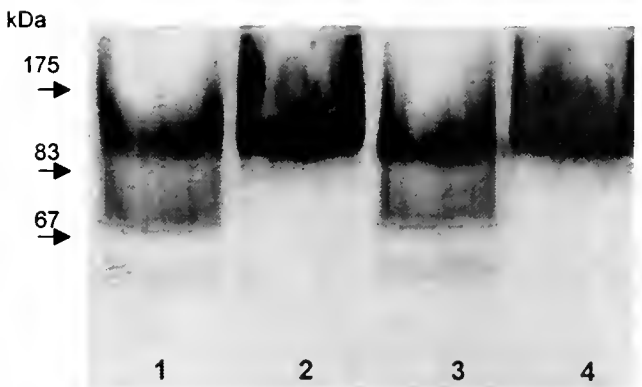

Figure 2. Inhibition of *V. antiqua* phosphatases. Phosphatase activity is inhibited when shellfish were fed with toxic *P. lima* (Lanes 2 and 4) as compared with control shellfish (Lanes 1 and 3). Molecular weight markers are as indicated.

phosphatase activity. The intensity of the stained band is proportional to the number of phosphatase molecules present in the gel band. Thus, Figure 1, Lanes 1, 3, and 5 show the shellfish protein phosphatase activity pattern obtained after analysis of tissue from uncontaminated shellfish. Upon feeding on organisms that synthesize DSP toxins, the protein phosphatase activity is reduced considerably, as shown in Figure 1, Lanes 2, 4, and 6. Furthermore, in *A. atter*, both protein phosphatases seem to be equally inhibited; whereas, in *M. chilensis*, the activity of the higher protein phosphatase band is more inhibited than that of the lower band. However, this pattern changes in *V. antiqua*, where the activity of the lower protein phosphatase band is inhibited, and the higher band shows increased activity (Fig. 1, Lane 6) with respect to the uncontaminated control shellfish (Fig. 1, Lane 5).

Dinophysis acuta has been shown to be a DSP toxin producer in Chile (Lembeye et al. 1991, Zaho et al. 1991). Unfortunately, at present, no *D. acuta* cultures are available in Chile or elsewhere. Therefore, to demonstrate that DSP toxins caused the protein phosphatase inhibition observed on the SDS-PAGE, *P. lima* cultures were used to feed *V. antiqua*. In this experiment, two important considerations were taken into account. First, *V. antiqua* was selected, because its inhibitory protein phosphatase pattern is well defined as observed in Figure 1, Lane 6. Second, Quilliam et al. (1996) demonstrated that aged cultures of *P. lima* contain the highest concentrations of okadaic acid and DTX-1 toxins. When the protein phosphatase pattern from shellfish fed with toxic *P. lima* cells are analyzed (Fig. 2, Lanes 2 and 4), it can seen that they are similar to those observed in shellfish naturally contaminated with DSP toxins (Fig. 1, Lane 6). It is also possible to observe that the 140 kDa band has increased protein phosphatase activity when compared to the uncontaminated control band. Furthermore, this increase in protein phosphatase activity resembles the sample naturally contaminated with DSP toxins. The additional 50 kDa protein phosphatase activity band detected is considered as a degradation product during the sample processing of the 70 kDa protein band, because it is also inhibited. However, the possibility exists that this band corresponds to a new protein phosphatase that was not previously detected. Finally, the DTX-1 detection by LC-MS analysis indicates that this DSP toxin inhibited the 70 kDa phosphatase activity in *V. antiqua*. The presence of DTX-1 in Chilean shellfish naturally contaminated with DSP was reported by Zhao et al. (1991).

Okadaic acid is a potent inhibitor of the serine/threonine protein phosphatases PP1A, PP-2A, and PP-2B but has no effect on PP-2C (Cohen 1989). The acetonic shellfish extraction used to detect DSP toxins is performed only on shellfish digestive glands (Japanese Ministry of Health and Welfare 1981), because most DSP toxins are found in this tissue compartment (Lee et al. 1987). However, despite knowing this, there is no available report on how DSP toxins affect endogenous shellfish protein phosphatase, as we describe here. More importantly, a simple analysis of these endogenous protein phosphatase activities could be used as a simple and economical test to demonstrate the presence of DSP toxins in the shellfish.

DSP toxin retention is very low in *Argopecten irradians* as well as in *Mytilus edulis* when fed with *P. lima*, as reported by Bauder et al. (1996) and Pillet et al. (1995), respectively. According to these two groups, low toxicity could be attributed to the possibility that: (1) DSP toxins were not tightly bound to shellfish tissue; (2) *P. lima* cells were evacuated readily with shellfish feces; or (3) DSP toxins follow an "erratic" pattern and are subjected to bio-

conversions. However, based on our results, lower toxicity could also be explained by: (1) a lower number of protein phosphatase molecules acting as DSP binding protein at a given time; or (2) the presence in those shellfishes of a protein phosphatase less sensitive to OA, because OA inhibition varies according to phosphatase isoforms. For example, PP-1, PP-2A, and PP-2B require 20 nM, 0.2nM, and 5 μM of OA, respectively, to be inhibited (Cohen 1989). Therefore, the number of molecules of DSP toxins retained in the shellfish digestive gland may be proportional to the number of DSP-type phosphatase-sensitive molecules available. Thus, the number of OA and DTX-1 molecules bound to phosphatase molecules could correspond to the DSP shellfish toxicity. However, OA and DTX-1 concentration could also depend on such variables as their affinity for the binding protein, the number of newly synthesized protein phosphatase molecules susceptible of being inhibited, the expression of different OA and DTX-1 receptor-like molecules, and the number of phosphatase with or without OA and DTX-1 released during the digestion process by enzymatic or mechanical action or by biotransformations or by protein turnover.

We conclude that DSP toxins inhibit some endogenous shellfish digestive gland protein phosphatases. In addition, the potential exists that changes in the activity patterns of these protein phosphatase molecules could be used to monitor for the presence of DSP toxins in different shellfish species. This approach could become an economic, simple, and sensitive assay capable of detecting the presence of DSP toxins in individual shellfish and avoid troublesome purification steps. Such an assay could be established in most laboratories with minimal investment, allowing the analysis of up to 18 samples within a 4-h period. Finally, this approach could be useful for studies on DSP toxin retention, detoxification of toxic shellfish, and could serve as the target to generate transgenic shellfish resistant or insensitive to toxins causing DSP.

ACKNOWLEDGMENTS

We thank Dr. Stephen Bates from Fisheries and Oceans Canada, Gulf Fisheries Centre, Moncton, New Brunswick, Canada for his comments and suggestions during the writing of this manuscript. Thanks are also due to Dr. Michael Quilliam from Institute for Marine Biosciences, Nova Scotia, Canada, for evaluating the methanolic gel extract by LC-MS analysis. Special thanks to the P. Valenzuela and B. Méndez Foundation for its continuous support.

FIRST REPORT OF DIARRHETIC SHELLFISH TOXINS IN MAGELLANIC FJORDS, SOUTHERN CHILE

JUAN CARLOS URIBE,[1] CARLOS GARCÍA,[2] MARIELLA RIVAS,[2] AND NÉSTOR LAGOS[2]

[1]*Laboratorio Hidrobiología, Instituto de la Patagonia, Universidad de Magallanes, Casilla 113-D, Punta Arenas, Chile;* [2]*Laboratorio Bioquímica de Membrana, Dept. de Fisiología y Biofísica, Facultad de Medicina, Universidad de Chile, Casilla 70005, Correo 7, Santiago, Chile*

ABSTRACT Diarrhetic shellfish poisoning (DSP) is a gastrointestinal disease caused by polyether toxins produced by dinoflagellates and accumulated in shellfish. Until now, in Chile, harmful algal blooms associated with DSP have been confined to north of 46°00′S. Following a bloom of Dinophysis sp., in Estero Nuñez (53°19′S, 72°30′W) in March 1998, phytoplankton and mussel samples were collected for qualitative and quantitative analysis. Dinophysistoxin-1 (DTX-1), a diarrhetic shellfish toxin, was identified and quantified in extracts of *Mytilus chilensis* Hupe, a chilean native filter bivalve. DTX-1 was measured using precolumn derivatization high-performance liquid chromatography method with fluorometric detection. The presence of DSP toxins was determined by a commercial colorimetric Protein Phosphatase assay (VDM-Test), which proved successful for the rapid screening of shellfish to detect DSP toxins. Okadaic acid was not detected in any mussel samples; the mussel shells showed only the presence of DTX-1, ranging from 65.0–583.8 ng of DTX-1 per gram of mussel digestive gland. This is the first report and quantitative analysis of DSP toxins in the Magellan region and extends 500 miles to the south, the known distribution of DSP toxins in Chilean coasts. The phytoplankton quantitative analysis showed *Dinophysis acuminata* (Clarapéde & Lachmann) as the most probable source of the DSP toxin.

KEY WORDS: *Dinophysis* sp., *Dinophysis acuminata*, DSP toxins, Dinophysistoxin-1 (DTX-1), HPLC toxin profiles, Patagonic fjords, southern Chile

INTRODUCTION

Proliferation of some microalgae in marine waters can contaminate seafood, cause massive fish kills, and alter ecosystems in ways that humans perceive as harmful. These events are generically referred to as harmful algal bloom (HAB). Surveys of affected regions, economic losses, and human poisoning throughout the world demonstrate a dramatic increase in the negative impacts of HABs over the last few decades and that the HAB problem is now widespread (White 1988, Anderson 1989, Smayda 1992, Hallegraeff 1993, Proenca et al. 1997, Lagos 1998).

A broad classification of HABs distinguishes two groups of organisms: the toxin producers, which can contaminate seafood or kill fish even if cell density is low, and high biomass producers, which do not produce toxins but cause deleterious impacts on the environment in other ways, such as through the consumption of oxygen, the production of scums, the reduction in habitat for fish or shellfish, or indiscriminate kills of marine life after reaching dense concentrations. Some HABs have characteristics of both. Although HABs occurred long before human activities began to transform coastal ecosystems, a survey of the affected regions and of the economic losses and human poisonings throughout the world demonstrates that there has been a dramatic increase in the negative impacts of HABs over the last few decades (Hallegraeff 1993, Lagos 1998).

Until now, six important human illnesses associated with microalgae toxins have been described worldwide (Hallegraeff 1993, Yasumoto & Murata 1993, Yasumoto et al. 1995, Falconer 1996). Two of these illnesses are present in Chile: paralytic shellfish poisoning (PSP) and diarrheic shellfish poisoning (DSP), both very well documented (Lembeye et al. 1975, Muñoz et al. 1992, Zao et al. 1993, Uribe 1993, Lagos et al. 1996, Lagos et al. 1998, Compagnon et al. 1998).

The first record of PSP was documented in 1972 in the Magellan region (~48°–56°S), the most austral region of Chile (Guzman et al. 1975, Lembeye et al. 1975), but PSP outbreaks have taken place continuously since 1991 (~42°–55°S.), causing many economic and public health problems (Uribe 1993, Lagos 1998).

Outbreaks associated with DSP have also occurred in the Patagonic fjords since 1970, but until now they have been limited from 46°S north. Historically, the northern part of the Patagonic fjords (more northern than 46°00′S) have been affected with DSP, including localities close to Puerto Montt city (41°27′S, 72°57′W) and some areas in the Aisen Region (~44°–48°S.). Here, some of these outbreaks have been associated with the presence of *Dinophysis acuta* Ehrenberg (Zhao et al. 1993, Lembeye et al. 1993).

Some other species of Dinophysis sp. have been mentioned elsewhere as DSP toxin producers, among them *D. acuminata* Clap. & Lach. and *Phalachroma rotundatum* Clarapéde y Lachmann (Muñoz et al. 1992, Steindinger 1993). Both species, but especially the first one, are very common in the phytoplankton of magellanic fjords (Uribe et al. 1998).

Attempts to evaluate DSP toxins in the Magellan region have been limited to the use of mouse bioassay, mainly in samples from localities near Puerto Eden village (49°20′S) in the northern part of the Magellanic fjords. All of the evaluations were done by a regional monitoring program for preventing poisonings. However, positive results for DSP have been inconclusive for two major reasons: they have not been associated with the presence of toxic or potentially toxic phytoplankton species, and the deaths of mice have been produced without any evidence of gastrointestinal symptoms.

In this paper, we address the presence of DSP toxins in an endemic Chilean filter-feeding bivalve mollusc (*Mytilus chilensis* Hupe) collected in an austral Magellanic fjord during a bloom of Dinophysis sp. This is the first report and quantitative analysis of DSP toxins in this southern remote area in the Magellan region.

MATERIALS AND METHODS

Phytoplankton and Mussel Sampling

Sampling for collecting material was done in Estero Nuñez (53°19′S, 72°30′W) (Fig. 1). A permanent hydrographic station is

maintained close to the sampling site as part of a regional monitoring program for shellfish poisons. The first two visits, in the frame of this program, were scheduled for January 26 and March 23, 1998. At the first visit, we found evidence of water discoloration in the fjord in a patch of . ~½ square mile. A net hauling was transported to the laboratory where the presence of abundant Dinophysis cells was detected.

This finding encouraged a second visit to the fjord, which took place on March 6 in a Chilean Navy Coast Guard vessel. The location where the discoloration was observed was divided into four parcels for sampling (Fig. 1). A set of phytoplankton and shellfish samples was obtained from each parcel. Mussel samples (*M. chilensis*) were collected from an intertidal zone, packed in plastic bags, labeled, and put into the vessel's freezer. Later, the samples were maintained at −20°C until toxin analysis was performed.

Phytoplankton samples for qualitative analysis were taken by vertical hauling of a 20-μm mesh net. A hose displayed in the first 10 m of water column was used to take integral samples for quantitative analysis. Both types of samples were fixed with Lugol's solution. Net samples were observed in normal microscope and quantitative samples in an inverted microscope (Hasle 1978). At least 400 cells per sedimentation chamber were counted.

Mussel Extraction and Analytical High-Performance Liquid Chromatography

Frozen hepatopancreas of mussels (2.0 g) were extracted two times with 3 ml of chilled 80% methanol under mechanical stirring using a tissue tearor (BioHomogenizer M 133/2280; Biospec Products, Inc., Bartlesville, OK). After centrifugation (1,500 × *g* for 5 min), one third of the supernatant (~2.5 ml) was diluted with water to a final concentration of 26.66% methanol. From this dilution, 5 ml were transferred to a C_{18} Sep-Pak cartridge, washed with 5 ml of 50% methanol (discard), and then 5 ml of pure methanol was added to elute the DSP toxins. This eluate was evaporated to dryness under reduced pressure in a Speed Vac Plus (Savant, SC 210A, Farmingdale, NY). The solid residue was treated with a freshly prepared solution of 0.1% ADAM (in 100 μl of acetone and 400 μl of methanol) (Lee et al. 1987). After 1 h at 25°C in the dark, the sample was evaporated to dryness, and the residue was diluted in 200 μl CH_2Cl_2/hexane (1:1) and then applied into a Silica gel cartridge column. The system was washed successively with 5 ml of CH_2Cl_2/hexane (1:1) and 5 ml CH_2Cl_2 and eluted with 5 ml of CH_2Cl_2/methanol (1:1). The last fraction was evaporated to dryness, dissolved in 1 ml methanol, and 10 or 20 μl were analyzed by high-performance liquid chromatography (HPLC). The HPLC conditions were Microsorb-MV C_{18} column (5 μm, 25 cm × 4 mm), mobile phase CH_3CN/methanol/H_2O; 8:1:1 isocratic, flow rate 1 ml/min, and the detection was done by a fluorescence detector (RF-535; Shimadzu), 365 nm (ex.) and 415 nm (em.).

Protein Phosphatase Inhibition Assay

Due to the high sensitivity of the detection, the presence of DSP toxins were also tested using the method based on the enzyme inhibitory activities of Protein Phosphatase 2A (PP2A) (Takai & Mieskes 1991, Rivas et al. 2000). We used two assays, a commercial colorimetric protein phosphatase assay called VDM-Test (TEPUAL S.A., Santiago, Chile) and a second one using the PP2A purified by our laboratory. The PP2A was purified from the filter

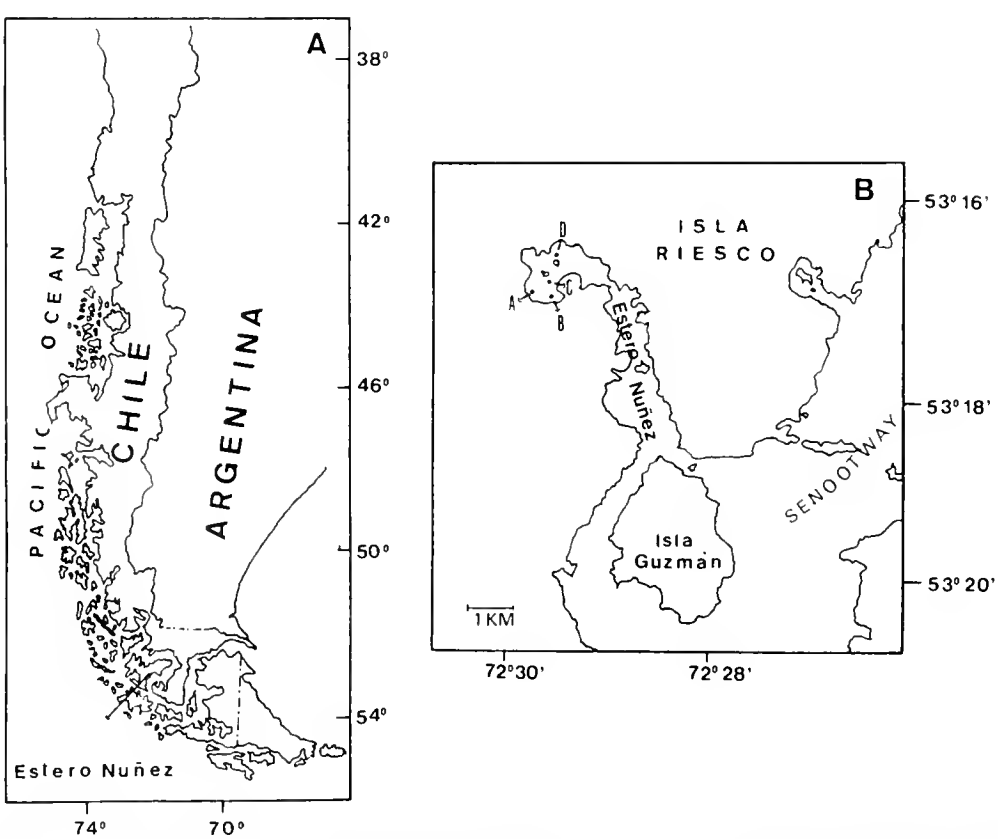

Figure 1. A. Map of Patagonic fjords. B. Sampling location: Sites A, B, C, and D in Estero Nuñez (53°18′00″S, 72°29′00″W).

bivalve *M. chilensis* as described by Rivas et al. (2000). The substrate mixture containing 22 mM *p*-nitrophenyl phosphate (Sigma Chemical Co., St. Louis, MO), 200 mM Tris/HCl, 20 mM EDTA, 20 mM DTT, and 2 mM $MgCl_2$ (pH 8.31) was mixed with enzyme solution, and the initial rate of liberation of *p*-nitrophenol was measured by recording the change in absorbance at 420 nm in a Beckman spectrophotometer model 25 with a pen recorder (Beckman Instruments, Fullerton, CA). The samples or PP2A inhibitors as positive control were mixed with the enzyme solution 5 min prior to initiating the reaction. Okadaic acid (OA) and Microcystin-LR (both from Sigma Chemical Co) were used as the specific inhibitors for PP2A activities. Complete inhibition was observed with 5 ng of Microcystin-LR or OA. All assays were carried out at 22–24°C. Each determination was done in duplicate. The reaction was stopped with 25 µl of methanol (Rivas et al. 2000).

RESULTS

Phytoplankton Distribution

Sampling on March 6 was made under high cloudiness, which did not permit us to distinguish any water discoloration. A total of 21 diatoms and 23 dinoflagellates, including a cystic form, were observed in the net samples collected (Table 1). The inner station showed the lower species richness (12 spp.), and the others ranged from 23 to 35 spp., most of them dinoflagellates. *D. acuminata* and *P. rotundatum* were detected in these samples.

Cell contour variation of *D. acuminata* seen in the samples showed some deviation from the characteristic oval or elliptical form typically found in Magellanic waters (Fig. 2). Antapex shape varies from rounded (Fig. 2a) to slightly acute (Fig. 2d), having in all cases two or three small protuberances. The light photomicrographs clearly illustrate that the Dinophysis sp., collected in the four stations of monitoring, correspond to *D. acuminata*.

Quantitative samples showed an absolute predominance of *Mesodinium rubrum* Lohmann (Table 1). Dinoflagellate was the second group best represented, and diatoms were present in scarce number (Table 2). From the dinoflagellates, *Gyrodinium lachryma* (Meunier) (Kof. & Swezy) was the most abundant, followed by *Polykrikos schwartzii* (Bütschli) and *D. acuminata*. The concentration of *D. acuminata* ranged from 600–960 cells/l in the four sampled sites. *P. rotundatum* was also present in these samples, although in lower concentrations (Table 1).

Identification and Quantitative Analysis of DSP Toxins

HPLC with fluorescence detection is the most suited approach for the quantitative analysis of DSP toxins. In our study, we used a detection system involving a precolumn derivatization of DSP toxins with a fluorescent chromophore 9-anthryldiazomethane, ADAM (Lee et al. 1987), which allowed us to detect nanogram quantities of DSP toxins. Figure 3A shows a typical chromatogram of DSP reference toxins, such as OA, dinophysistoxin-1 (DTX-1), and the internal standard deoxycholic acid (DEO), showing retention times (Rt) of 9:60, 13:20, and 18:40 min, respectively, for the 9-Anthrylmethyl esters.

Figure 3B shows the chromatographic properties of the extract obtained from the mussel sample collected in site A (see Fig. 1b and Table 2). The elution profile showed a single peak indistinguishable from 9 MA-DTX-1 (Fig. 3A), with a Rt = 13:20 min. All samples extracted and analyzed showed the same elution profile, displaying DTX-1 as the only DSP toxin present in the samples. The amounts of DTX-1 measured by the HPLC analysis of each sample collected in the four sites of Estero Nuñez are showed in Table 2. These values were confirmed by inhibition of

TABLE 1.

Phytoplankton concentration (cells/l) in Estero Nuñez (53°19′00″S, 72°30′00″W).

PP2A assays. The extracts of mussel samples collected from sites A, B, and C showed inhibition over PP2A, the amounts of DSP toxin calculated from the inhibition curve using the mussel extracts were the same measured by HPLC (Table 2).

DISCUSSION

From the low phytoplankton concentrations and the absence of water discoloration it is possible to infer that the sampling done in March 6 was made in a period after a bloom. Samples came from the head of a small, enclosed fjord that receives fresh water discharge from two creeks, so the water column stability is a typical situation in this area. During the monitoring visit, done on January 26 and March 23, the temperature and salinity were recorded from a monitoring station located approximately 2 miles from the sites where samples were collected. These data showed a low density in surface water with an average temperature of 11.18°C and a mean salinity of 28.78 psu in January. During the monitoring visit of March, these parameters were 9.14°C and 29.49 psu, respectively. At both sampling visits a pycnocline at approximately 5 m depth was observed. According to the literature, such stability is a condition that permits planktonic dinoflagellates and ciliates to reach high densities (Margalef et al. 1979, Holligan 1985).

D. acuminata is one of the seven species of Dinophysis sp. that have been confirmed to produce OA and/or DTX-1 (the other six species are *D. fortii* Pavillard, *D. acuta*, *D. norvegica clarapede* & *Lachmann*, *D. mitra* (Schutt) Abé, *D. tripos* Gourret, and *Ph. rotundatum*; Lee et al. 1989). The quantitative analysis of phytoplankton samples collected in the Estero Nuñez showed two possible sources of DSP toxins: *D. acuminata* and *P. rotundatum*. *P. rotundatum* is the most likely source because it showed the

DTX-1 = dinophysistoxin-1; OA = okadaic acid; ND = none detected.

higher cell density. *D. acuminata* is a common species in the phytoplankton of the Magellanic fjord waters (Uribe et al. 1998). The variation of the contour found this time in the *D. acuminata* cells is not common in the Magellanic fjords, but it adjusts quite well in the range presented by Balech (1976) in a study of Norwegian Dinophysis.

Estero Nuñez has the typical geomorphology of small Magellanic fjords, with the water column stability as the most common hydrographic feature. Consequently, small toxic blooms could be frequent along the region and probably are being overlooked by monitoring programs because sampling stations are located far from the fjord heads. In fact, mussels gathered in the head of Estero Nuñez caused eight human cases of PSP in April 1989 in this region (Uribe 1989, Lagos 1998). A similar situation occurred with mussels collected in the head of Bahía Nash, in March 1991, where there were 95 human cases of PSP and two deaths (Uribe 1992, Lagos 1998).

Historically in our country, HABs associated with DSP have been confined to Patagonic fjords north of 46° S. Now, this finding extends the known DSP toxins distribution approximately 500 miles further to the South of Chile in the Austral Magellanic fjords.

The frequent presence of Dinophysis sp. in Magellanic fjord waters, now associated with DSP toxins, represents a latent threat to the public health, which demonstrates the need to develop a more thorough evaluation for the presence of DSP toxins and its primary source in many small fjords along the Magellanic region. This is especially important after the demonstration that DTX-1 causes severe injuries on the intestinal mucosa (Terao et al. 1986). Furthermore, another important aspect of OA and DTX-1 is their potent tumor-promoting activity (Suganuma et al. 1988), so attention should be paid to the continuous uptake of subacute levels of DSP toxins through seafood.

ACKNOWLEDGMENTS

This study was supported by FONDECYT 1961122 and Fundación Andes. Also, we want to thank the Chilean Navy for allowing us to cruise in the Coast Guard vessel LPC Villarrica to collect the samples on March 6. Miss Marcia Vera drew the map.

ABSTRACT The king scallop, *Pecten maximus*, is a valuable economic resource in the UK. The industry relies on supplying premium "roe-on" processed scallops to the continental market. In July 1999, king scallops harboring the amnesic shellfish poisoning (ASP) toxin, domoic acid (DA), in gonadal tissue at levels above the regulatory limit (20 μg DA g^{-1}) were detected across a wide area of northern and western Scotland. In response, a survey of the southern extent of the closed harvest areas was initiated to describe variability of ASP toxin levels over varying spatial scales (<5 m to >5 km); determine the anatomical distribution of the toxin, and identify, isolate, and culture causative *Pseudo-nitzschia* species. Toxin analysis was conducted using a liquid chromatography-tandem mass spectroscopy (LC-MS/MS) procedure. The DA content of tissues followed the predictable rank order: all other tissue → gonad → adductor. The toxin levels within all other tissue (95% CI = 580–760 μg DA g^{-1}, n = 170) consistently accounted for 99% of the total individual toxin burden. DA levels in the gonad (95% CI = 8.2–11.0 μg DA g^{-1}, n = 170) were an order of magnitude below levels in all other tissue and contributed to less than 0.5% of the total individual toxin burden, although levels above the regulatory limit were detected in individual gonad samples. Adductor muscle tissue contained the lowest concentrations of DA (95% CI = 0.38–0.82 μg DA g^{-1}, n = 170), and was typically within two to three orders of magnitude below levels in all other tissue. None of the scallops examined had DA toxicities in adductor muscle tissue exceeding the regulatory limit. Toxin variability among individuals and sites was high (range of coefficients of variation (CV) in all other tissue = 29%–120% and gonadal = 45%–85%). The results do give an indication of the scale on which microhabitat differences may influence ASP toxicity in *P. maximus* populations, because significant differences were found in all other and gonadal tissue toxin levels between groups of individuals only 25-m apart. In total, seven species of *Pseudo-nitzschia* were identified from west coast waters. A suspected causative species, *P. australis*, was found to produce high levels of DA, in culture. The high individual variation in toxicities and the occurrence of DA in the gonad at levels above the regulatory limit clearly demonstrate the complexity of managing the king scallop fishery during ASP events.

KEY WORDS: amnesic shellfish poisoning, domoic acid, *Pseudo-nitzschia*, *Pecten maximus*, scallop fishery

INTRODUCTION

Marine algal toxins comprise a diverse group of biologically active compounds with high acute toxicities in humans (Shumway & Cembella 1993). Scallops, opportunistic filter feeders exploiting both pelagic and benthic microorganisms as food sources, are liable to the accumulation and concentration of phycotoxins from toxic algal species present in the water column (Shumway et al. 1987, Bricelj & Shumway 1991). The risk of human illness as a result of toxic scallop consumption poses a significant threat to both public health and shellfish industries (Shumway & Cembella 1993).

Amnesic shellfish poisoning (ASP), a relatively new type of seafood toxicity, was first described from Prince Edward Island, Canada, in 1987 (Bates et al. 1989). Over 100 people who consumed mussels contaminated with a naturally occurring neuroexcitatory toxin, domoic acid (DA), experienced gastroenteritis and neurological symptoms (Wright et al. 1989, Todd 1993). In this first episode, the source of the domoic acid was identified as the pennate diatom, *Pseudo-nitzschia pugens* f. *multiseries*, which was ingested and accumulated by the mussels during normal filter feeding (Bates et al. 1989). Global awareness of ASP has since been raised, and, to date, ASP toxin-producing species of *Pseudo-nitzschia* have now been reported from the gulf of Mexico region, North America, Canada, Europe, Australia, Japan, and New Zealand (Hallegraeff 1995). From laboratory studies, it is now clear that several species of *Pseudo-nitzschia*, and two species from separate genera (*Amphora* and *Nitzschia*), are capable of producing DA, but the levels of production are highly variable (Kotaki et al. 2000, Bates 2000, Lundholm & Moestrup 2000).

The king scallop, *Pecten maximus*, is a valuable economic resource in the UK. The UK scallop industry is principally a wild fishery exploited by scallop dredgers, which account for an estimated 97% of UK landings. However, small quantities are landed by divers, and in Scotland, there is an emergent aquaculture industry. The industry is largely reliant on supplying premium "roe-on" processed scallops to the continental market. In 1998, 9,700 tons of *P. maximus* were landed in Scotland, with a first sale value of £15.5 million, equating to approximately 25% of all EU scallop landings (Denton 1999). An estimated 95% of the king scallops are processed as meat and roe product, of which 60% is distributed as premium chilled product and 40% frozen. Dive collected and farmed scallops are sold whole to a smaller, yet higher value market for live shellfish.

The incorporation of systematic ASP/domoic acid testing of shellfish into the Food Standards Agency (FSA) Scottish waters surveillance program was initiated early in 1999. By July 1999, *P. maximus* harboring DA in the gonad at levels above the internationally accepted closure limit (20 μg DA g^{-1}) were detected across a wide area of northern and western Scotland. This prompted a widespread closure of the king scallop fishery, which persisted in excess of 9 months, resulting in financial hardship for scallop dredging, diving, and cultivation industries. The nature of

the ubiquitous and prolonged high toxicity seemed to be confined to the king scallop, because only sporadic, short-term toxicities were noted in the queen scallop, *Aquipecten opercularis*, and negligible levels detected in other shellfish (FSA pers. comm., 1999). The direct cost to the industry to date has been estimated at £10 million, and the loss of skilled processing staff and disruption of established supply routes to continental markets led to serious concern for its survival (Denton 1999). The restriction on all scallop landings provoked controversy, stimulating much media interest. To date, there has been no documented history of human illness caused by ASP in the UK.

In response, an opportunistic survey of the southern region of the closed harvest areas was initiated to provide fundamental information on the ASP incident. The objectives were to: describe ASP toxin variability among individual and neighboring scallop populations over varying spatial scales (<5 m to >5 km); determine the anatomical distribution of ASP toxin within scallop body parts: adductor muscle and gonad, and all other tissue (digestive gland, mantle, gill); assess any influence of size, age, and depth on scallop toxicity levels; and isolate, culture, and identify causative *Pseudo-nitzschia* species. The data collected provide basic information to assist with the development of rational management strategies to continue to protect public health while minimize the economic constraints of future ASP events.

TABLE 1.

Overall mean and standard error (SE) DA levels (μg DA g^{-1} wet weight) in the adductor, gonad, all other tissue and total tissue of *P. maximus* collected from the three locations.

Tissue	*n*	Mean	SE	Minimum	Maximum	CV (%)	95% CI	no. >20 μg g^{-1}	no. >1000 μg g^{-1}
Adductor	170	0.60	0.114	0.011	15.42	247	0.38–0.82	0	—
Gonad	170	9.58	0.722	0.131	75.5	98	8.16–11.01	19	—
All other	170	669	45.7	0.2	3689	89	580–760	169	10
Total	170	295	19.3	0.9	1569	85	256–333	168	8

Ninety-five percent confidence intervals (CI), minimum and maximum levels of DA obtained, coefficient of variation (CV %) and number of individuals with toxin burdens >20 and >1000 μg DA g^{-1} are given.

MATERIALS AND METHODS

Sampling

In December 1999, 10 specimens of adult *P. maximus* (shell height >90 mm) were collected by SCUBA at three subsites (total of 30 individuals) within Loch Sligachan (57°15′5′ N 06°15′5′ W) and at four subsites (total of 40 individuals) within Tobermory Bay (56°35′5′ N 06°05′5′ W) (Fig. 1). To provide an assessment of ASP toxin levels among scallop populations on a larger spatial scale, in context with the current monitoring program; a third sampling location, the scallop fishing box-Area J5, was included in the sampling regime (Fig. 1). Twenty adult scallops (shell height >90 mm) were selected at random from the landings dredged from each of five subsites (total of 100 individuals). These locations were routinely used for the monitoring of ASP toxin under the Food Standards Agency Program and were chosen as a result of previously consistent high DA levels (above the 20 μg DA g^{-1} statutory level) within scallop gonad. Upon collection, all scallops were individually sealed in zip-lock polythene bags, placed in cool boxes, and transported to the Scottish Association for Marine Science (SAMS) Laboratory within 6–12 h, for immediate dissection.

The age of each scallop was estimated by enumerating shell growth bands and shell length and breadth (Mason 1983) measured to the nearest 0.1 mm. The scallops were dissected into the body components: adductor muscle, gonad, and all other tissue (digestive gland, mantle, and gills). Special care was taken to avoid artifactual contamination from adjacent tissues, by careful dissection, washing, and drying of individual body components. The digestive material of the intestinal loop within the gonad was physically removed. All body components were weighed to the nearest 0.001 g, sealed separately in zip-lock polythene bags, and frozen at −20°C before DA extraction (Quilliam et al. 1989).

DA Extraction and Quantification in Scallop Tissue

Tissues were homogenized in a blender (3 min), which was cleaned and rinsed with methanol and then distilled water, between each sample. Four grams of tissue homogenate was rehomogenized (4 min) with 10 mL of 100% methanol, centrifuged (10 min at 5,000 rpm), and a 5-mL subsample of the resulting supernatant filtered through a disposable 45-μm filter membrane. The extract was stored at −20°C before DA detection and quantification.

The extracts were evaporated to dryness using vacuum centrifugation and resolubilized in 50/50 methanol and water before triplicate analysis. The samples were analyzed on a liquid chromatography-tandem mass spectrometry (LC-MS/MS) system consisting of an Agilent Model 1100 high-performance liquid chromatography (HPLC) system, coupled to either a SCIEX API-III triple quadrupole or a Finnigan LCQ ion trap mass spectrometer. The chromatography was performed on a C18 reversed phase column with a 0.2 mL/min flow of a 1–95% gradient of methanol:

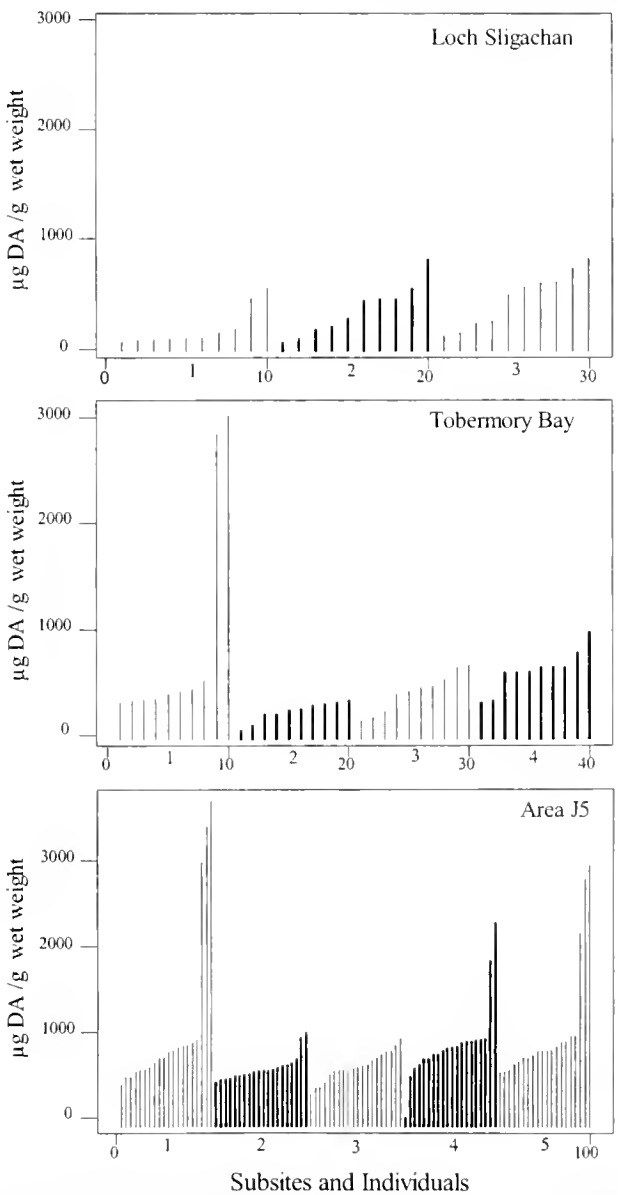

Figure 2. DA toxicity levels (μg DA g^{-1} wet weight) in all other tissue of *P. maximus* collected from subsites within locations.

water. All solvents had 0.1% trifluoroacetic acid added. A portion of the effluent from the HPLC system was directed into the electrospray ionization source of the mass spectrometer via a flow splitter. The mass spectrometer was operated in positive mode with [M+H]+ ions (−312 m/z) being isolated in a first stage of MS analysis. The isolated ions were subjected to "collision- induced dissociation" reaction conditions, which are expected to stimulate the fragmentation of the [M+H]+ ions into characteristic product ions. All quantitations were based on the integrated chromatographic intensity areas of one of the fragment ions (at 267 m/z), and the appearance of other characteristic ions was used as confirmatory evidence for the DA ion's identity (Scholin et al. 2000).

Phytoplankton Sampling and Isolation

During August and October, plankton tows were taken from Orkney, Dunstaffnage, and Jura, to record *Pseudo-nitzschia* spp. presence. In December, at each subsite within Loch Sligachan and Tobermory Bay, surface plankton trawls, quantitative water samples (NIO bottle, at 5 m), cores (water/sediment interface samples), and benthic sediment samples were taken to examine the vertical distribution of *Pseudo-nitzschia* spp. present. At the subsites within Area J5, plankton trawls and quantitative water samples with (NIO bottle, at 5 m) were performed. Four replicates of each sample were obtained from each site; of which two were preserved with Lugol's iodine for cell counts, and two were enriched by addition of f/2 + Si growth medium. Samples were examined for actively growing chains of *Pseudo-nitzschia* cells and candidate chains of cells isolated by micro-pipette and repeated washing in sterile f/2 growth medium. Individual chains of cells were incubated with f/2 + Si growth medium (Guillard & Ryther 1962) at 15°C under an approximate light intensity of 50–80 μmol PAR m^{-2} s^{-1} (12:12 light/dark cycle). Stock cultures were grown for three weeks (stationary phase) before cell harvest by gentle centrifugation (1,500 rpm), followed by removal of excess growth medium and resuspension in sterile growth medium. Samples of cell pellets and supernatant were immediately placed on ice before DA analysis.

DA Extraction and Quantification in Pseudo-nitzschia *spp.*

Cell pellets were subjected to ultrasonication (10 min) in 50/50 methanol and water, before filtration (Whatman filter, 0.2 μm). The supernatant samples were directly filtered using the same filter size. The crude extract or filtrate from the supernatant was analyzed using HPLC coupled to a diode-array detector (10 μL injected). The system (Thermoquest) comprised a solvent reservoir and degasser, P4000 pump, AS3000 autosampler, and UV 6000 diode-array detector. The HPLC column was a VYDAC 201TP54 (250 × 4.6 mm, 5 μm) with a VYDAC guard column 201GK54T (10 × 4 mm, 5 μm). The mobile phase was 0.1% trifluoracetic acid in 10% aqueous acetonitrile, at 1.5 mL/min flow rate. The column temperature was kept at 40°C. Wavelengths monitored ranged from 200–360 nm, and spectral confirmation was obtained by comparison of sample spectra to those from the certified reference standard DACS-1C. Quantitation was carried out at a wavelength of 242 nm.

RESULTS

Anatomical Distribution

Despite the considerable variation in toxin levels within each body compartment, DA loading of the tissues followed a predictable rank order: all other → gonad → adductor. The toxin levels within all other tissue consistently accounted for 99% of the total DA burden. A small proportion of individuals had DA levels in all other tissue (>1,000–3,690 μg DA g^{-1}) an order of magnitude greater than mean levels (669 ± 45.7 μg g^{-1}). Mean DA levels (μg

Means from the same location with different superscripts are significantly different ($P > 0.05$, Kruskall–Wallis and Dunn's method). Ninety-five percent confidence intervals (CI), minimum and maximum levels, coefficient of variation (CV %) and number of individuals with toxinburdens >1000 μg DA g^{-1} are given.

g^{-1}) in gonad tissue were an order of magnitude below levels in all other tissue, and, on average, contributed to less than 0.5% of the total individual toxin burden. DA levels above the statutory 20 μg DA g^{-1} safety level in gonads were detected in 22% of the scallops examined, although these values were not encompassed within the 95% confidence limits (8.16–11.01 μg DA g^{-1}, $n = 170$). Adductor muscle contained the lowest concentrations of DA and was typically two to three orders of magnitude below levels in all other tissue while accounting for only 0.17% (mean) of the total individual toxin burden. Although the CV (247%) of individual adductor muscle DA levels was observed to be considerably greater than all other and gonad tissues (98 and 89%, respectively), none of the scallops examined, had adductor muscle toxicities that exceeded the statutory limit, and 95% of the samples had levels below 1.9 μg g^{-1}.

A weak, positive correlation was observed between $\log_{10}$ all other tissue toxicity and $\log_{10}$ gonadal toxicity ($r = 0.303$, $P < 0.001$, $df = 169$); whereas, no correlation could be found between DA concentrations in all other and adductor muscle tissue. No significant correlation could be made between DA toxicity in the three body compartments and scallop age and size parameters.

Spatial Distribution

At all sites, a large variation in all other tissue toxin levels between individuals was observed (Fig. 2), indicated by the CV values (Table 2). However, significant differences in all other tissue toxin levels among locations were distinguished. Scallops from Area J5 had significantly greater levels of DA in all other tissue than individuals from Tobermory Bay and Loch Sligachan; whereas, no significant differences in toxin levels were found between scallops from Tobermory Bay and Loch Sligachan.

Significant differences in toxicities between individuals from different subsites within the same location were observed at all the three locations. Within Tobermory Bay, all other tissue DA toxin levels differed significantly between neighboring scallop populations 25 and 1,200 m apart (subsite 2 DA levels were significantly lower than 1 and 4). In scallops from Loch Sligachan, all other tissue DA toxin levels differed between neighboring scallop populations 300 m apart (subsite 3 DA levels were significantly higher than 1). Within the scallop fishing box, Area J5, all other tissue DA toxin levels were significantly higher in scallops from subsites 4 and 5 than 2 and 3, collected 8–12 km apart. Scallops with high all other tissue toxin burdens (>1,000 μg g^{-1}) were not evenly distributed among locations or subsites. The significance of the results remained unchanged, regardless of the removal of individuals with high toxicities from the dataset.

At all sites, a large variation in gonadal toxin levels between individuals was observed (Fig. 2), indicated by CV (Table 3). Despite the wide variation, gonadal toxicity among locations followed the same pattern of the toxicity as all other tissue, because scallops from Area J5 had significantly greater levels of DA in the gonad than individuals from Tobermory Bay and Loch Sligachan. Similarly, no significant differences in gonad toxin levels were found between scallops from Tobermory Bay and Loch Sligachan.

Significant differences in DA levels between subsites of the same site were observed at all threesites sampled. In Tobermory Bay, gonad DA toxin levels differed between neighboring scallop populations 25-and 1,200-m apart (subsite 2 and 3 DA levels were significantly lower than 1). In Loch Sligachan, gonadal DA toxin levels differed between neighboring scallop populations 300 m

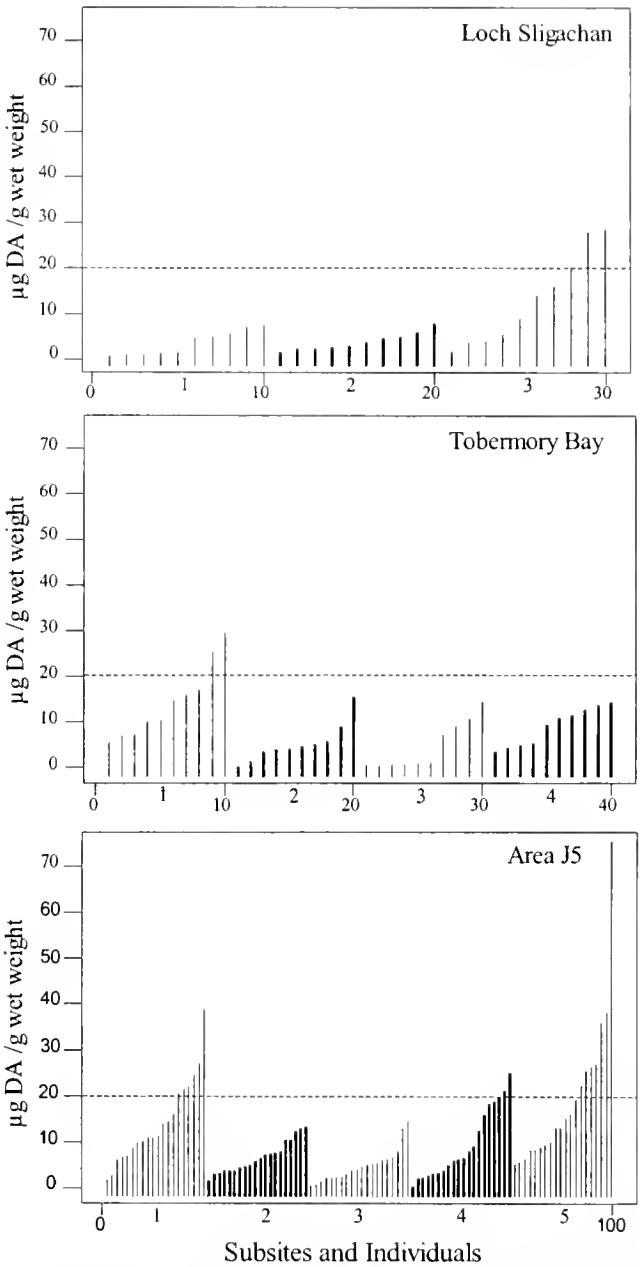

Figure 3. DA toxicity levels (μg g^{-1} wet weight) in the gonad of *P. maximus* collected from subsites within locations. Line = statutory limit (20 μg DA g^{-1} of tissue).

apart (subsite 1 DA levels were significantly higher than 3). Within Area J5, gonadal DA toxin levels were significantly higher at subsite 5 than at 2, 3, and 4; whereas, gonad toxicity in subsite 1 was greater than that in 3. At each location, scallops with gonadal toxicities exceeding the 20 μg DA g^{-1} limit were encountered. However, the frequency of these individuals was not homogenous among the subsites, ranging from 0 out of 20 individuals (Area J5, subsites 2 and 3) to 7 out of 20 (Area J5, subsite 5).

Scallops from Tobermory Bay had significantly lower levels of DA in the adductor muscle than individuals from Loch Sligachan and Area J5. Levels of toxicity among locations did not correspond to the pattern of toxicity seen in all other and gonad tissue. No significant differences in adductor muscle toxin levels were found

Means from the same location with different superscripts are significantly different ($P > 0.05$, Kruskall–Wallis and Dunn's method). Ninety-five percent confidence intervals (CI), minimum and maximum levels of DA obtained, coefficient of variation (CV %) and number of individuals with gonadal toxin burdens >20 μg DA g^{-1} statutory limit are given.

between scallops from Loch Sligachan and Area J5. At all sites, an exceptionally large individual variation in adductor muscle toxin levels was observed (Fig. 4), indicated by the CV (Table 4).

Within Tobermory Bay, adductor muscle DA toxin levels differed between neighboring scallop populations 25- and 1,200-m apart (subsite 3 DA levels were significantly lower than 1). In Loch Sligachan, no significant differences in adductor muscle toxin levels were observed between subsites. In Area J5, adductor muscle toxin levels were significantly higher in scallops in subsite 5 than in 2 and, 3, and toxicity in subsite 1 was greater than in 2. Again, the significance of the results remained unchanged, regardless of the removal of individuals with a comparatively high toxin loading.

Pseudo-nitzschia *spp. Abundance and DA Production*

The August to October plankton tows samples showed several potentially toxic *Pseudo-nitzschia* species were present. At the peak of the blooms, *P. australis* was the dominant species followed by *P. pungens*. Several other species were present as minor components: *P. multiseries*, *P. seriata*, *P. delicatissima*, *P. fraudulenta*, and *P. pseudodelicatissima*. The blooms were observed to subside during October 1999, with low levels of *P. delicatissima* persisting through to December 1999. At the time of scallop collection (December 1999) *Pseudo-nitzschia spp.* cell numbers were exceptionally low throughout the water column (<1 cell/mL) at the sites sampled (water temperature range 7–9.5°C). These cell concentrations are well below that usually associated with reported ASP events. Examination of surface sediments at Loch Sligachan and Tobermory Bay also failed to detect significant quantities of living or dormant cells *Pseudo-nitzschia spp.*

Three *Pseudo-nitzschia* cultures were established from samples collected in the August 1999 blooms, two strains of *P. australis*, and one of *P. pungens*. Stationary growth-phase cultures of both *P. australis* strains produced detectable levels of DA in intracellular and extracellular fractions (Table 5). However, the presence of DA could not be detected in the *P. pungens* cultures (detection limit = 0.1 μg mL^{-1} in cell/supernatant extracts). In both *P. australis* cultures, total DA was partitioned with approximately one- third being intracellular and two-thirds present in the growth medium.

DISCUSSION

The trend in body component toxicity of *P. maximus* as a proportion of total scallop toxin burden (all other tissue → gonad → adductor), is in agreement with previous studies of DA in *P. maximus* (Arevalo et al. 1998), DA in *Placopecten magellanicus* (Douglas et al. 1996), and paralytic shellfish poisoning (PSP) in *P. magellanicus* (Cembella et al. 1994). In the current study, 99.4% of individuals had levels of DA in all other visceral tissue over the statutory 20 μg DA g^{-1} limit. The maximum DA concentration in all other tissue (3,689 μg DA g^{-1}), recorded in this study was approximately 180 times the regulatory limit (20 μg DA g^{-1}) and is among the highest levels recorded in bivalves. Arevalo et al. (1998) found the highest levels of DA in the hepatopancreas in *Pecten maximus* (maximum = 2,083 μg DA g^{-1}). Similar high levels (approximately 3,000–4,000 μg DA g^{-1}) were found in the digestive gland of *Placopecten magellanicus* (cited in Douglas et al. 1996). Thus, the levels of DA found in all other tissue in the present study are consistent with previous findings, confirming that DA is predominantly sequestered within the digestive gland in *P. maximus*.

Toxin levels of gonadal tissue were generally lower than the statutory 20 μg DA g^{-1} limit; however, toxicities above this level were encountered. Adductor muscle toxicity contributed negligible amounts to the total body burden, and levels never exceeded the statutory limit, even when toxin levels were extremely high in all other tissue. The occurrence of PSP toxins in adductor muscle is

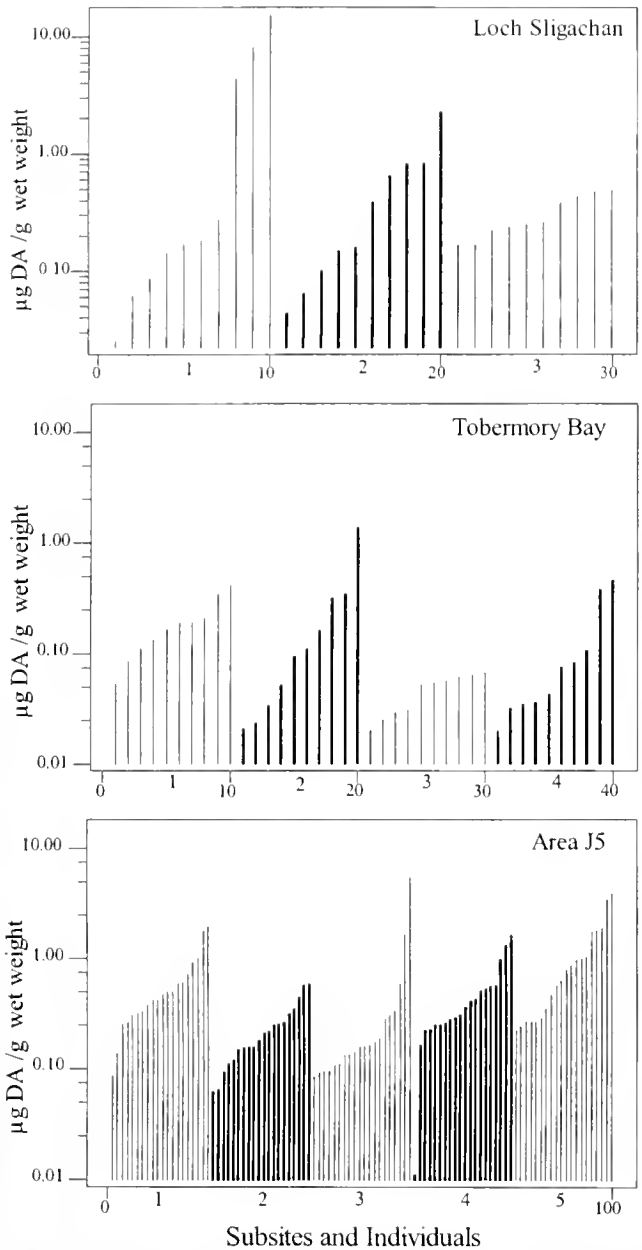

Figure 4. DA toxicity levels (µg DA g^{-1} wet weight) in the adductor muscle of *P. maximus* collected from subsites within locations, plotted against a $\log_{10}$ scale.

rare; and in the scallops *P. magellanicus*, *Patinopecten yessoeniss*, and *Crassodoma gigantea*, adductor muscle PSP toxicity is always at least 10-fold less than in corresponding digestive tissue (cited in Shumway & Cembella 1993). Bricelj and Shumway (1998) report that, during PSP events, such tissues involved in locomotion as the muscular foot, adductor muscle, and pallial muscles, invariably attain toxicities two to three orders of magnitude below those in the viscera, and contain a minimal proportion, typically < 1% of the total toxin loading, despite their relatively large mass in some species. However, Pacific razor clams, *Siliqua patula*, are reported to sequester DA principally within muscular tissue (Drum et al. 1993).

Confirmation of DA production by *Pseudo-nitzschia australis* and its dominance during the blooms indicate this species was one of the primary sources of scallop ASP contamination in 1999. Although a co-dominant species, *Pseudo-nitzschia pungens*, did not produce detectable concentrations of DA in culture, it is possible that other *Pseudo-nitzschia* species, with known DA production capabilities and present as minor components, may have contributed to the ASP event (e.g., *P. seriata*, *P. fraudulenta*, or *P. pseudodelicatissima*). The dominance of P. australis observed in the west coast waters, was not confirmed for other affected areas. Lundholm et al. (1994) showed *P. seriata* produced DA at low temperatures, thus it could potentially represent a source of DA in colder, northern Scottish waters. The DA concentration of the 1999 Scottish isolates of *P. australis* (3–4 pg total DA $cell^{-1}$) compare closely with previous studies of *Pseudo-nitzschia*, as cellular DA levels are reported to range from 0.1–10 pg DA $cell^{-1}$ for most species studied to date (cited in Bates 1998). Previous studies of western North American *P. australis* have indicated comparatively high DA production capabilities (12–37 pg DA $cell^{-1}$, Garrison et al. 1992). However, our data are more consistent with estimates of 2.0 pg DA $cell^{-1}$ for New Zealand strains (Rhodes et al. 1996), and with unpublished data from Spanish and Irish *P. australis* strains (S. Bates, Fisheries and Oceans, Canada, pers. comm. 2000).

It is likely that the 1999 DA toxification, measured in December 1999, in Scottish king scallops occurred as a result of *Pseudo-nitzschia* blooms during the May to August 1990 period and not the result of continuous intake from toxic benthic sources (Bourne 1965), because *Pseudo-nitzschia spp.* concentrations were very low during October and December, and no significant quantities of living or dormant *Pseudo-nitzschia* cells were detected within the locations at time of sampling. Therefore, the current results support the hypothesis that high DA levels in scallops are a consequence of low rates of toxin catabolism as a result of low winter basal metabolic rates and reduced filtration activity, further influenced by colder waters and reduced food supply (Shumway & Cembella 1993).

The considerable degree of toxin variability observed among individual *P. maximus* and their body components was not unexpected and has been described for other shellfish species contaminated with DA and PSP toxins (White et al. 1993, Arevalo et al. 1998). Characterizing variation in toxin levels among individual species of the same area is necessary both for ecological considerations and for development of sound management protocols (White et al. 1993). The results do give an indication of the scale on which microhabitat differences influence ASP toxicity in *Pecten maximus* populations, because, despite wide individual variation, significant differences were found in all other tissue and gonadal toxin levels between groups of individuals only 25 m apart. Variation in bivalve toxicity is reported to result from an interaction of such factors as timing, persistence, and magnitude of toxic blooms, microgeographic variation in exposure to toxic cells because of bloom patchiness, the specific toxicity per cell, and toxin composition of the contaminating organism, environmental effects on scallop metabolism, and, perhaps, genotypic differences among scallop populations (Bricelj & Shumway 1998). However, the reasons for the few individual scallops retaining exceptionally large toxin burdens in all other tissue (>1,000–3,689 µg DA g^{-1}) are not known.

The ability to detect influences of scallop size parameters on DA accumulation may have been restricted by the limited size class (90–120 mm shell length; i.e., legal landing size) selected for use in the current study. Expanding the range of sizes used to

Means from the same location with different superscripts are significantly different ($P > 0.05$, Kruskall–Wallis and Dunn's method). Ninety-five percent confidence intervals (CI), minimum and maximum levels of DA obtained, coefficient of variation (CV %) and number of individuals with adductor muscle toxin burdens >20 μg DA g^{-1} statutory limit are given.

include juveniles may indicate any allometric influences on DA toxin accumulation in *P. maximus*. Under controlled conditions, weight-specific DA toxicity has been demonstrated to be inversely proportionate to body size in mussels *Mytilus edulis* (Novaczek et al. 1992). However, faster detoxification rates per unit body mass in actively growing, smaller, or younger individuals, because of toxin dilution through growth, may mask any allometric relationships present (Bricelj & Shumway 1998).

A significant positive correlation was observed between toxicity of the gonad and that of all other visceral tissue. Although little is known about transfer of DA among tissues, its likely that gonadal toxicity is influenced by the level of digestive gland toxicity, via the intestinal loop, which passes through the gonad and may contain toxic feces. Cembella et al. (1993) demonstrated that PSP toxins are accumulated within gonadal follicles of *P. magellanicus*, even after the exclusion of the intestinal loop. However, the inherent wide individual variation precludes the ability to predict gonad toxicities reliably from routine ASP toxin monitoring of the viscera. Compared with other body components, the variation in adductor muscle toxicity was proportionately larger, and no correlation could be found between toxicity of the adductor muscle and that of all other tissue. The variance in toxicity values in adductor tissue may be attributed to one of, or a combination of, three sources: (1) natural variation in adductor muscle toxicity; (2) variable contamination of the tissue from digestive fluid, during dissection; and (3) analytical error close to the limits of detection. The mean CV accounted for by the detection method for all other tissue, gonad, and adductor muscle was ±11.8, 4.6, and 18.6%, respectively, indicating that the variability observed between individual scallops was not a result of analytical error. The extent to which toxic digestive fluid and exudates contaminates edible tissues should be established to ascertain the potential to reduce the ASP toxin burden by appropriate preparation of adductor muscle and gonad tissue and realize the necessity to standardize preparation of these tissues before testing.

During ASP events, the marketing of *P. maximus* digestive gland, mantles, and gills, poses a high risk to public health, which has an impact primarily on diver-based and cultivation industries supplying markets for whole scallops. However, to allow the marketing of the nontoxic edible component, scallop preparation techniques should be promoted, such as the immediate removal of toxic tissues and thorough washing of the edible component (having ascertained the gonad is safe to consume), and this practice should be regulated and conducted by skilled processing staff before the product reaches the consumer (Shumway & Cembella 1993; Curtis et al. 2000). Our results verify that strict regulatory and monitoring regimes should remain compulsory for the safe marketing of "roe-on" scallops. However, when gonad toxicities are greater than the regulatory limit, discarding of tissues that selectively sequester the DA toxin may provide an effective strategy to enable the marketing of adductor muscle, in conformity with the domestic "roe off" market of the United States and Canada (Bricelj & Shumway 1998).

The concentration of DA in gonad tissue varied by an order of magnitude (range 0.13–75.5 μg DA g^{-1}). Thus, if gonads with high toxicities were to be included in pooled samples, they could potentially elevate toxin levels significantly. This may explain why monitored toxicity at certain sites seemed to oscillate throughout the winter period (FSA pers. comm. 1999). Consequently, a large number of individuals should be included in composite samples to reflect mean population toxicity accurately. However, in species where toxicities are extremely variable, it is the consensus that monitoring tissues on an individual basis proves more informative in developing mitigating strategies for harmful algal bloom management. Curtis et al. (2000) were able to propose site-specific recommendations for management, on the basis of large differ-

ences in PSP toxicity among geoduck clams, *Panope abrupta*, of different depths and harvest tracts. Data describing individual variability of gonad toxicity within localities allow subpopulations with a low frequency of individuals of elevated gonadal toxicity to be distinguished (as seen in the current study); therefore, they permit evaluation of the level of risk, gonad tissue from specific locations with respect to its rate of consumption, poses to human health. The use of risk assessment models should be considered to assess scallop toxicity with respect to rate of consumption by humans, to continue to maintain public safety standards while at the same time ensuring optimum utilization of the high-quality king scallop resource.

ACKNOWLEDGMENTS

We thank Ms N. Lundholm (University of Copenhagen, Denmark) for the initial identification of *Pseudo-nitzschia* species and the members of the Scallop Association for their invaluable support and assistance. This study was funded by The Scallop Association, The Highlands and Islands Enterprise, PESCA, and The Highland Council.

STRANDING OF SCALLOPS RELATED TO EPIPHYTIC SEAWEEDS ON THE COAST OF NORTHERN CHILE

SERGIO A. GONZÁLEZ, WOLFGANG B. STOTZ, AND MARCELO AGUILAR

Departamento de Biología Marina, Facultad de Ciencias del Mar, Universidad Católica del Norte, Casilla 117, Coquimbo, Chile

ABSTRACT More than two million scallops (*Argopecten purpuratus* Lamarck) were stranded on the beach at Tongoy Bay, northern Chile (30°20′S) in March 1999 during a period of unusually strong wave action. The scallops, which were stranded in living condition, had frondose algae attached, principally *Ulva lactuca* Linneaus, to the upper valve. Settlement and growth of the algae on the scallop shells facilitated the stranding due to the large surface area thus exposed to water movement. A preponderance of larger size classes of scallops fouled with algae were stranded, suggesting that the epibionts decreased the chance of "escape" from the effects of water movement in relation to the size of the individuals.The stranding represented about 20% of the population of the bed. It is suggested that nearshore areas were mainly affected, where light conditions promoted the rapid growth of the epiphytic seaweeds.

KEY WORDS: scallop stranding, algal epiphytism, mass mortality, Chile

INTRODUCTION

Stranding and mass mortalities on the shore are frequent occurrences and affect distinct groups of marine organisms. There is a great deal of information on the stranding of marine mammals and turtles (Raga et al. 1991, Blochet al. 1997, Berrow & Rogan 1997). However, in the case of marine invertebrates, the literature is limited, particularly as it relates to Chile. For invertebrate strandings, many different causes are suggested. Natural mortality is cited for the strandings of the cnidarian *Velella velella* in Oregon (Kemp 1986). Some strandings are selective and affect a fraction of the population, as reported for the horseshoe crab (*Limulus polyphemus*), in which stranding is associated with senescence and parasitism in some individuals (Penn & Brockman 1995). In other cases it is related to changes in the environment, such as the mortalities produced by the El Niño phenomenon. This phenomenon has been implicated in strandings of the pelagic crab (*Pleuroncodes planipes*) (Aurioles et al. 1994), as well as mollusks (*Mesodesma donacium*) and brown algae of the genus Macrocystis (Arntz & Valdivia 1985, Arntz et al. 1985). Major storms and high tides may cause stranding, as in the case of the lobster (*Homarus americanus*) on the coast of Prince Edward Island, Canada (Maynard & Chiasson 1988) and the yellow clam (*M. mactroides*), of which millions were stranded in Argentina (Oliver et al. 1971). Other strandings include those related to pollution, such as oil spills (Dyrynda et al. 1997).

Strandings of scallops, resulting from strong winds and storms or due to consequences of disease, parasitism, or senescent states, have been reported (Tettelbach 1985, Orensanz et al. 1991). Tettelbach (1991) reported strandings of the scallop *Argopecten irradians* (Lamarck, 1819) in the Poquonock River in Connecticut, which was associated with strong wave and tidal currents. If the scallops are stranded live, they die due to desiccation, bird predation, and human harvesting.

Tettelbach (1991) included the anecdotal case of a stranded scallop having an abundant covering of the alga (Codium) on its shell. However, this is not an isolated phenomenon, as shown by the report of Kelley and Kirby (1981), who related an extensive stranding of the bay scallop on Nantucket Island, Massachusetts due to *Codium fragile*. Galtsoff (1964) called the epiphytic Codium "oyster thieves." Ansell et al. (1988) related a major stranding of the sandy bottom clam *Donax vittatus* (da Costa) in Dornach, Scotland, to the growth of algae on their shells. Similarly, Orensanz et al. (1991) mentioned that the risk of stranding in *Chlamys tehuelcha* (Patagonia, Argentina) was increased by the presence of epibionts.

The present report describes a stranding of the scallop *A. purpuratus* (Lamarck) on the coast of northern Chile, produced by swell-induced waves, and the facilitation of the stranding by the presence of epibiotic algae on the scallops.

MATERIALS AND METHODS

Study Area

Observations were made at Puerto Aldea (30°17′S, 71°36′W), a small locality at the extreme southern end of Tongoy Bay, which is protected from the predominant southwest winds by Lengua de Vaca Point (Fig. 1). However, with north winds it experiences a major swell. Off Puerto Aldea, the bottom is composed of sand and rocky areas and a sector covered by the seagrass (*Heterozostera tasmanica*), which forms a bed of approximately 1.5 hectares (Phillips et al. 1983, Gonzalez 1992). The scallop (*A. purpuratus*) is distributed over the entire Puerto Aldea area (Stotz & Gonzalez 1997), which is protected and managed by local fishermen.

Methods

During a period of unusually high swells on the northern coast of Chile in March 1999, 221 stranded scallops (*A. purpuratus*) were collected from a strip of beach at Puerto Aldea. The shell height (dorsoventral length) of the scallops was measured to ±1 mm. The total fresh weight of the scallops was obtained using the relationship of size to weight determined for this region by Stotz and Gonzalez (1997): Weight (g) = $2.897 \times 10^{-4} \times$ Height $(\text{mm})^{2.905}$.

The occurrence of algae attached to the shells of each individual was recorded, both in cases where the entire thallus was present or where there was evidence of algae (e.g., holdfast). Given the characteristics of the algae encountered, our work cen-

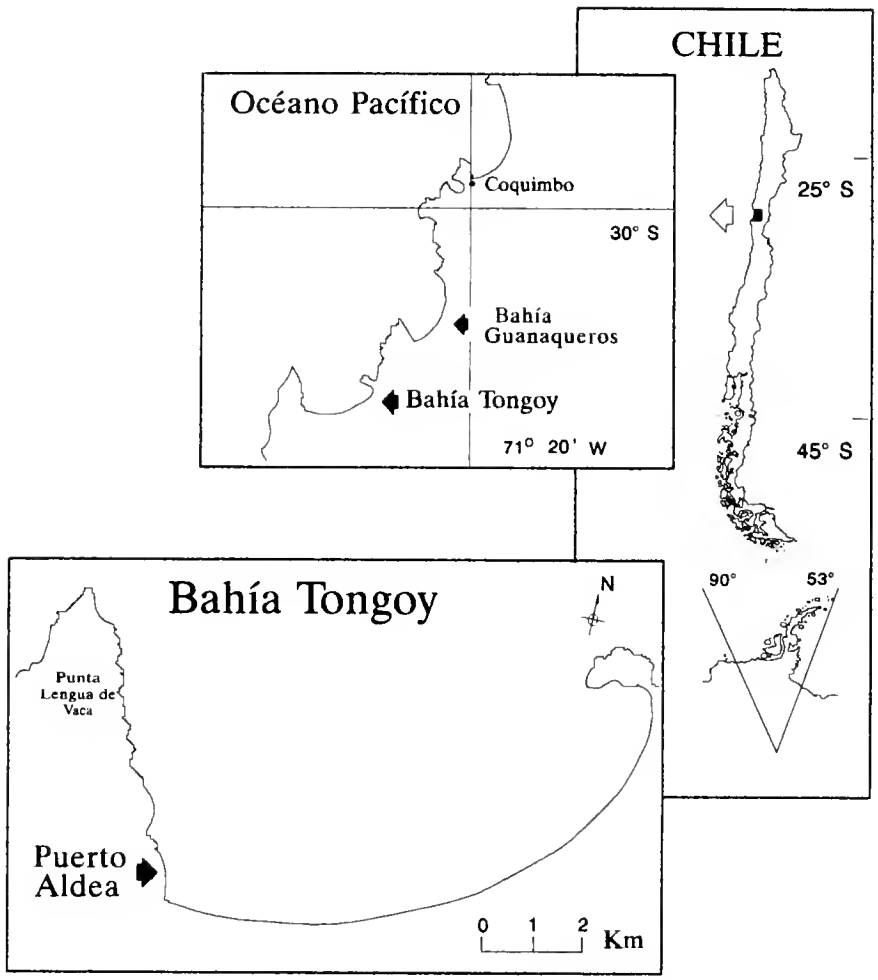

Figure 1. The location of the scallop stranding at Tongoy Bay, northern Chile.

tered on the most abundant alga, *Ulva lactuca* Linneaus (1753). Algae were measured for maximum length from adhesive disc to the end of the longest frond (±1 mm), and wet weights were measured to ±0.1 g on a portable balance. Algal surface area was determined using the equation 1 g wet weight of *U. lactuca* = 89 cm^2, obtained by weighing 30 algal pieces cut to 16 cm^2 (0.18 g).

An estimate of the magnitude of the stranding was obtained by personal interviews with fishermen at Puerto Aldea. Their determination was made on the basis of the number of scallops that they collected and from their estimates of the numbers of scallops removed from the beach by people from outside the Puerto Aldea community.

RESULTS

Stranded Scallops

Sixty-five percent of the stranded scallops bore an algal thallus on the shell, with a further 20% showing the presence of a holdfast or a partial algal thallus. The remainder of the scallops had no macroalgae attached to their shells.

Although a wide size range of scallops were stranded (Fig. 2), most of the scallops collected ranged from 40–80 mm in shell height. Scallops with algal epibionts were somewhat larger than those without epibionts (Table 1). A median *t* test showed significant differences in the sizes of the scallops in these groups (t value$_{(73)}$ = 5.1338, $P < 0.001$).

Characteristics of Algal Epibionts

Algae on the scallops included principally *U. lactuca*, with the occurrence of only seven individuals of *Cryptonemia obovata* (J. Agardh, 1876) and one of the brown alga *Desmarestia ligulata* (Lightfoot) (Lamouroux, 1813).

Fronds of Ulva on the scallop shells had a broad range of sizes,

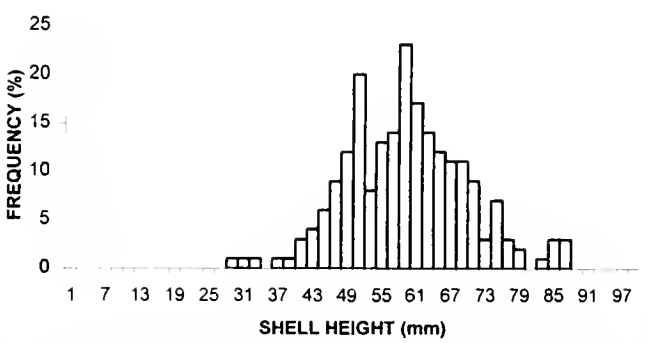

Figure 2. Size–frequency distribution of *Argopecten purpuratus* stranded at Puerto Aldea, Chile in March 1999.

TABLE 1.

Percentage of different size groups of scallops (*Argopecten purpuratus*) stranded at Puerto Aldea, Tongoy Bay, Chile, in March 1999.

	Range of sizes (shell height, mm)											
	Total		0–20		21–40		41–60		61–80		81–100	
Epibiont status	*n*	%	*n*	%	*n*	%	*n*	%	*n*	%	*n*	%
With algae	190	80.2	0	—	3	60	89	79.5	81	91	7	100
Without algae	33	19.8	0	—	2	40	23	20.5	8	9	0	—

ranging from 34–971 mm in length, with an average length of 378 mm (Fig. 3). Fronds frequently exceeded 170 mm in length. The surface area of the fronds ranged from 98–6,803 cm^2, and the weight ranged from 1.1–76.1 g.

Scallop–Algae Relationship

A tendency was observed for the algae on the scallop shells to be larger on the larger sizes of scallop. Although there was a broad dispersion of values, this relationship was statistically significant via linear regression ($F_{0.05(1,136)} = 46.5$, $P < 0.001$) (Fig. 4).

Magnitude of the Stranding

Because of their commercial value, the scallops did not accumulate on the beach; they were harvested by a great number of people and taken away for sale. A survey of 43 persons at Puerto Aldea who harvested scallops produced a total of 217,550 scallops. This harvesting extended over the 4 days during which the stranding occurred. Estimates by the fishermen's association of Puerto Aldea indicated that about 1,700 other people visited the area of the stranding and removed a total of about 2 million scallops. On the basis of the sizes of scallops stranded, we estimated the total fresh weight of scallops removed to be about 100 metric tons.

DISCUSSION

The higher incidence of stranded scallops bearing algal epibionts than those without epibionts demonstrated the importance of algae to the stranding of scallops during the period of heavy swell. Observations made by diving after the passage of the stranding event (M. Aguilar, pers. observ.) showed an almost complete absence of algae-bearing scallops remaining in the bed, suggesting that essentially all epibiont-affected scallops had been beached by the waves. It was probable, due to the light requirements of the green algae, that the beached scallops came mainly from shallow areas near the shore, which would be more subject to water movement. However, it is also possible that the swell ripped off the epiphytic Ulva fronds from the shells of the scallops.

Although the stranding was associated with heavy swells that affected Puerto Aldea when winds of about 10 m/s and waves of about 2 m in height occurred for several hours (Chilean Navy data), the stranding was facilitated by the presence of algae on the scallop shells. For example, an alga 50 cm in length with a surface area of 1,700 cm^2 on a scallop 6 cm in height represents an increment of 40× the surface area of this scallop normally exposed to water movement.

The fact that large scallops not bearing epibionts were generally absent from the stranding suggests that these scallops were able to escape the effects of water movement by virtue of their size (weight), whereas scallops with algal growth on the shells were transported to the shore. This concurs with the observations of Witman and Suchanek (1984) that the presence of algae such as *Lauminaria saccharina* and other epibiota on the shells of *Mytilus edulis* and *M. californianus* significantly increased their risk of being dislodged by currents.

The stranding may be related to climatic alterations related to the El Niño phenomenon, both in reference to the heavy swells and the abundance of green algae occurring in this period. Also, changes in sea state that produce unusual wave action may be accompanied by rises in sea surface temperature associated with El Niño currents and provide improved conditions for algal growth. For example, Arntz et al. (1985) reported blooms of frondose green algae, which grew rapidly during the El Niño event of 1982–83 and dominated rocky shallows on the coast of Peru.

An evaluation of the scallop bed at Puerto Aldea carried out 2 mo after the stranding (Stotz & Gonzalez, unpub. technical report) showed the presence of about 8 million scallops. The stranding

therefore represented a loss about 20% of the population (previous to the swell period) from this bed. However, in addition to the observed effects of the stranding of scallops on the natural population, this event could have a negative effect on the perception of the local fishermen about the benefits of protecting the resource. Nature took away almost 20% of their possible income. Although the stranded scallops were harvested, it was mainly by foreign people, not by members of the Puerto Aldea community. This needs to be evaluated.

ACKNOWLEDGMENTS

The authors are grateful for collaboration rendered by the fishing community of Puerto Aldea, who aided in collecting information on the numbers of scallops stranded and harvested. We also thank M. Valdebenito and D. Lancellotti of the Ecology and Resource Management Group (UCN) for their helpful comments and Louis DiSalvo for translation and editorial comments. An anonymous referee is thanked for providing valuable suggestions.

REPRODUCTION, POPULATION STRUCTURE, AND RECRUITMENT LIMITATION IN A BAY SCALLOP (*ARGOPECTEN IRRADIANS* LAMARCK) POPULATION FROM NEW JERSEY, USA

PAUL A. X. BOLOGNA,[1]* AMI E. WILBUR,[2] KENNETH W. ABLE[1]**

[1]*Institute of Marine and Coastal Sciences, Rutgers University Marine Field Station, 132 Great Bay Blvd., Tuckerton, New Jersey 08087-2004;* [2]*Florida Marine Research Institute, 100 8th Ave S.E., St. Petersburg, Florida 33716*

ABSTRACT A bay scallop, *Argopecten irradians irradians* (Lamarck 1819), population was studied in Little Egg Harbor, New Jersey, USA to investigate the distribution, reproduction and genetic structure of the population because virtually nothing is known about this species in this region. *Argopecten irradians irradians* densities varied among eelgrass (*Zostera marina* Lamarck) beds in 1998 (range 0.12–1.0 individuals per 10m transect), but were virtually absent from the region in 1999. The absence of adults in 1999 may have been due to limited spat recruitment and survival in the fall of 1998, which may be attributed to a reduction in above ground biomass of *Z. marina* habitat. Genetic analysis (using mtDNA) indicated that this New Jersey population was intermediate between New York and North Carolina populations. Based on these data and the historical landings of bay scallops in New Jersey, it is probable that a small self-seeding population exists. Assessment of reproductive cycles during 1998 showed two potential peaks in reproductive condition: one occurred during June when a maximum Gonadal-Somatic Index was recorded (24.7%) and the second was during October when a visual gonadal condition index indicated a majority of scallops in post-spawn condition. Few adult bay scallops were encountered in 1999 ($n = 8$) to assess reproductive cycles, but two large individuals collected during July showed a post-spawn gonadal condition. However, during both 1998 and 1999 settling juveniles (< 15 mm shell height) were only recorded in October, suggesting that recruitment to the population during these years resulted from the late summer-early fall spawn. Given the variability observed over the two years, future studies should concentrate on factors influencing inter-annual variation in abundance of this New Jersey population.

KEY WORDS: bay scallop, *Argopecten irradians*, reproduction, genetic structure, recruitment

INTRODUCTION

The bay scallop (*Argopecten irradians*) was once a common and often abundant member of shallow marine communities along the Atlantic and Gulf coasts of the United States and a prized commercial and recreational shellfish. Clarke (1965) identified three distinct sub-species of *A. irradians* based on morphological characteristics, but recent morphological and genetic studies have suggested a fourth (Blake and Graves 1995, Marelli et al. 1997, Wilbur and Gaffney 1997). The northern sub-species, *A. i. irradians* ranges from Massachusetts to New Jersey where it is thought to intergrade with the southern subspecies *A. i. concentricus*. *Argopecten irradians concentricus* was originally described to range along the mid-Atlantic coast and into the Gulf of Mexico (Clarke 1965, Waller 1969). Recent studies, however, have shown that bay scallops from the Florida gulf coast and from North Carolina are as different from one another as are the northern and southern subspecies on the Atlantic coast, indicating that these populations should be considered distinct subspecies (Blake and Graves 1995, Marelli et al. 1997, Wilbur and Gaffney 1997). The fourth subspecies, *A. i. amplicostatus*, is occasionally reported from the gulf coast of Texas and extends to an undefined southern limit south of the Yucatan Peninsula. This sub-species has been described solely on the basis of morphological analysis and the scarcity of animals in recent years has constrained the incorporation of representatives in the aforementioned genetic surveys. A preliminary analysis of the mitochondrial DNA variation does not support the separation of *A. i. amplicostatus* from other Gulf populations despite the clear demonstration of genetically determined differences in morphology (Wilbur 1995, Wilbur and Gaffney, 1997). As such, the taxonomic status of the western gulf form of *A. irradians* is unclear.

Bay scallops are intimately tied to seagrass beds, which they use as a primary settlement site (Gutsell 1930, Eckman 1987). Specifically, scallops settle and cling to blades via byssal threads until they are too large to remain suspended (Thayer and Stuart 1974). During this life stage, the seagrass canopy provides protection from benthic predators (Pohle et al. 1991). However, reduced growth rates of juvenile scallops climbing higher on blades (Ambrose and Irlandi 1992), suggests that this behavior may represent a trade-off between growth and mortality. Ultimately, recruitment to the adult population may be determined by predation at this juvenile stage (Strieb et al. 1995). Because bay scallops recruit to seagrasses and use them as attachment sites (Thayer and Stuart 1974), the loss of habitat during the eelgrass (*Zostera marina*) wasting disease in the 1930s (see den Hartog 1987) is thought to have severely limited populations in many regions, while eliminating them from others. Although eelgrass has made recoveries in the subsequent decades (den Hartog 1987), bay scallops have not returned in significant numbers to many areas where they once were abundant. In coastal New Jersey, eelgrass has returned and is relatively abundant in shallow water, yet in the last several decades bay scallop densities remain below a fishable population size (Ford 1997).

Historically, bay scallops were abundant and commercially fished in New Jersey, USA. The first available landing records were collected in 1956, when 52,300 bushels were harvested with an estimated value of $287,000. Continued success of scallop populations for the next 12 years yielded 317,000 bushels valued at over $1 million (Ford 1997). Subsequently, commercial bay scallop harvests were only recorded for 1973 and 1974. Despite its

local importance, little information exists on the ecology and population structure of New Jersey bay scallops, particularly since the collapse of the commercial fishery. In recent years it was generally felt that bay scallops no longer occurred in New Jersey waters. The observation of numerous scallops in 1998 in Little Egg Harbor, New Jersey prompted questions regarding the density and reproductive periodicity of this population, as well as its origin. New Jersey is thought to be the point of contact between the *A. i. irradians* and *A. i. concentricus* sub-species, and the return of scallops suggests recruitment of larvae from extant populations north or south of New Jersey, or from a small, remnant local population. It was the goal of this research to investigate the distribution, reproduction and genetic structure of New Jersey bay scallops.

STUDY SITE

Investigations were conducted during 1998 and 1999 in Little Egg Harbor, New Jersey, U.S.A. (39°35′N, 74°14′W; Fig. 1), which is located in the central portion of the Mid-Atlantic Bight. Little Egg Harbor is a relatively unimpacted region of coastal New Jersey and is part of the Jacques Cousteau National Estuarine Research Reserve (Psuty et al. 1993). It is a polyhaline estuary protected by a barrier island. It is relatively shallow (average depth at MLW = 1.7 m, Durand 1984) and submerged aquatic vegetation covers approximately 1,305 hectares of the bottom (Bologna et al. 2000). Seasonal water temperatures range from −2°C to 28°C (Able et al. 1992) with an average tidal range of about 0.7 m (Chizmadia et al. 1984).

MATERIALS AND METHODS

Population Assessment

Argopecten irradians densities were assessed at four sites in Little Egg Harbor, New Jersey during May 1998 and 1999. Density was determined using 10-m × 1-m transects haphazardly lain out in shallow (< 1.5m depth) *Zostera marina* beds (Table 1,

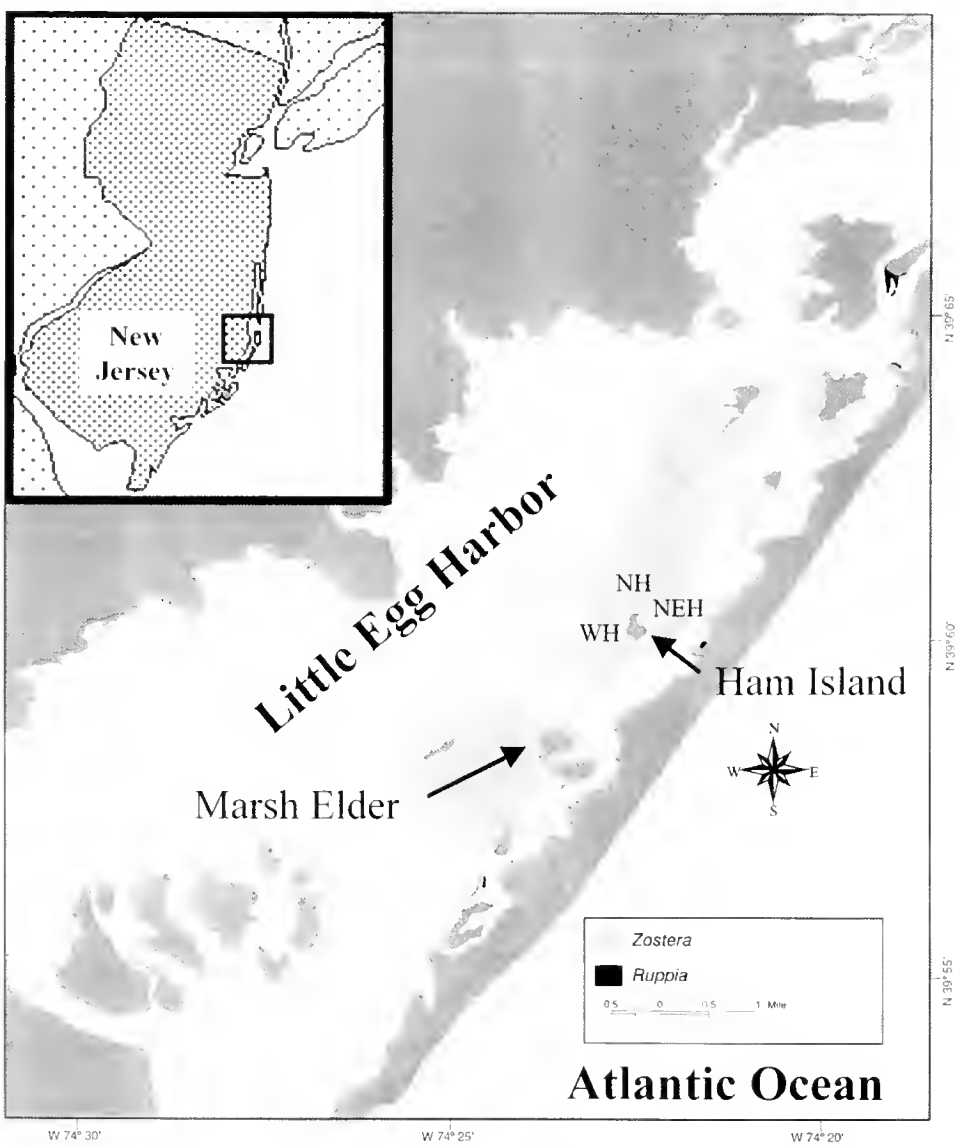

Figure 1. Little Egg Harbor, New Jersey (39 35′N, 74 14′W) with locations of Marsh Elder and Ham Island and dominant vegetation types. Abbreviations associated with Ham Island refer to sites used for population density estimates: WH = West Ham Island, NH = North Ham Island, NEH = Northeast Ham Island.

Fig. 1): (1) West Ham Island (n = 16 transects, 1998; n = 10, 1999), (2) North Ham Island (n = 17; n = 10), (3) Northeast Ham Island (n = 14, n = 10), and (4) Marsh Elder Island (n = 8, n = 10). They were sampled by snorkeling the length of the transect and collecting all scallops within 50 cm of the transect line (1-m width). Scallop abundance was compared among sites and between years using a two-way ANOVA with site and year as independent variables and scallop abundance as the dependent variable. The size structure of the population was assessed monthly from visually located field-collected individuals during 1998. Size frequency distributions were generated for months in which at least 16 individuals were collected to assess the potential age structure of the population.

Reproduction

Visual inspection of the gonad condition and calculation of a Gonadal-Somatic Index (GSI) assessed scallop reproduction from collections on 10 dates from April 1998 to August 1999. Scallops were frozen and returned to the laboratory where shell height was measured to 0.05 mm and gonadal and somatic tissues were then dissected out. Visual condition of gonad material for scallops was determined for each individual and assessed as undeveloped, ripening, very ripe, or post-spawn following the protocol of Bologna (1998). Reproductive and somatic tissues were then dried at 60°C for 72 hours and weighed (g dry weight). The GSI was calculated for each scallop using the following equation: GSI = (gonad dry weight/total dry weight) *100. Evidence of reproductive success was assessed by collection of small juveniles (<15 mm shell height).

Recruitment Habitat Assessment

Characterization of bay scallop habitat was assessed by collections of benthic cores in *Zostera marina* beds during March, April, May, June, July, and October 1998 to determine shoot density and plant biomass (n = 6 cores/month). The coring device (15.24 cm diameter (0.01824 m^2)) was pushed into the substrate to a depth of 25 cm, capped, and removed from the sediment. Samples were frozen and returned to the laboratory. Shoot abundance was determined and samples were separated into *Z. marina* above ground (shoots) and below ground (rhizomes and roots) portions, and an algal-detrital fraction. Above ground *Z. marina* and algae-detritus were dried to constant weight at 80°C, then ashed at 500°C for eight hours to determine ash free dry weight (AFDW). Shoot abun-

dance data were square-root transformed and plant biomass data (*Z. marina* and algae-detritus) were log transformed before analysis. Shoot abundance, above ground biomass, and algae-detritus biomass were compared among months using a General Linear Model and significance testing was performed using an LSMEANS procedure with alpha = 0.05 (Littell et al. 1991).

Genetic Stock Assessment

Total DNA was extracted from 20 scallops collected in Little Egg Harbor during 1998 (PureGene extraction Kit, Gentra Systems, Inc) and amplified using primers specific for an 833bp fragment of the 12s ribosomal and NADH dehydrogenase 1 subunit regions of the mtDNA genome. Polymerase chain reaction (PCR) amplifications were carried out in 50μl reaction volumes and were subjected to an initial denaturation step of 3 min at 94°C, followed by 40 cycles consisting of 30 sec at 94°C, 30 sec at 53°C and 1 min at 72°C. Each product was digested with 9 restriction endonucleases (*Alu* I, *Ban* II, *Bgl* I, *Bsi*HKA I, *Rsa* I, *Hinf* I, *Scr*F I, α*Taq* I and *Tsp*509 I) following manufacturer's protocols (New England Biolabs, Beverly, MA). Digestion products were electrophoresed on 2% agarose gels and visualized using ethidium bromide.

Restriction fragment patterns were analyzed using the REAP (McElroy et al. 1992) and compared with data previously collected on scallop samples from New York (East Hampton), North Carolina (Core Sound, Bogue Sound), and Florida (Florida Bay, Homosassa, St. Joseph's Bay). For each of the seven populations sampled, nucleotide divergences were estimated and corrected for within population variation (Nei 1987). Sample haplotype frequency distributions were tested for heterogeneity using contingency tables and a randomized chi-square test of independence (Roff and Bentzen 1989). Population structure among scallop samples was analyzed using a hierarchical analysis of molecular variance (AMOVA, Excoffier et al. 1992).

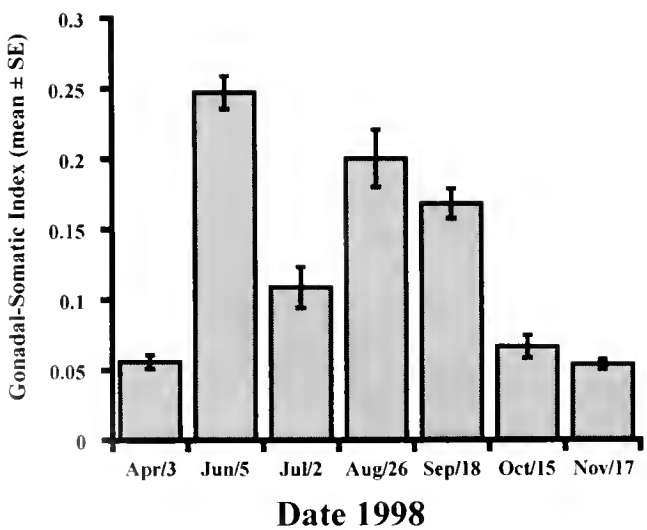

Figure 3. Seasonal Reproductive Assessment for 1998. Values represent calculated mean Gonadal Somatic Index ± Standard Error for scallops collected. See Table 2 for visual gonad condition index.

RESULTS

Population Assessment

During 1998, bay scallop densities were significantly greater from all Little Egg Harbor study sites compared to 1999 ($F_{1,87} = 24.6$; $P < 0.0001$), because no scallops were collected during 1999 transects (Table 1). As such, a significant interaction occurred between year and site in the two-way ANOVA ($F_{3,87} = 5.6$; $P < 0.001$). Therefore, we conducted a post-hoc ANOVA comparing scallop abundance among sites for 1998. Results indicated significant among site differences in scallop density ($F_{3,51} = 8.6$; $P < 0.0001$), with density significantly greater for the North Ham Island site (1.0 individual 10 m^{-2}) compared to the other sites (Table 1). Sufficient population samples were collected during April, June, September, October, and November 1998 to assess the size structure of the population (Fig. 2). Based on these data, a single year class (45–75 mm shell height) was identified but a few individuals of a second year class (6–12 mm shell height) occurred in October.

Reproduction

Visual assessment of gonad condition in 1998 suggested that spawning occurred during September and early October, as evi-

denced by the prevalence of post-spawn individuals in October (Table 2). However, this result differs with the assessment of GSI, which showed maximum values in June (Fig. 3), corresponding with 75% of the individuals showing a very ripe gonad condition (Table 2). Despite these very high GSI values, the presence of settling individuals (<15 mm shell height $n = 3$) was noted only for October. This was true for both 1998 (6 and 12 mm shell height, Fig. 2) and in 1999 (9 mm). Based on these preliminary data, the peak recruitment period for New Jersey *Argopecten irradians* may be early fall.

Recruitment Habitat Assessment

During 1998 significant losses of recruitment habitat, *Zostera marina*, occurred in Little Egg Harbor. Macroalgae (e.g., *Ulva*, *Gracilaria*, *Codium*) increased in abundance in eelgrass beds, blanketing the bottom. This led to significant increases in algal biomass by June, with significant loading of algal and detrital material by July and continuing through to October ($F_{5,25} = 13.3$, $P < 0.0001$, Fig. 4). These changes to the system resulted in significant declines in eelgrass shoot density and biomass by July 1998 ($F_{5,25} = 11.4$; $P < 0.0001$, $F_{5,25} = 8.9$, $P < 0.0001$), with complete elimination of above ground *Z. marina* biomass in the study area by October 1998 (Fig. 4).

Genetic Stock Analysis

A total of 22 haplotypes were resolved in the analysis of 120 *Argopecten irradians* from the six populations between New York and Florida (Table 3). Haplotype diversity (the probability that a pair of individuals sampled from a population were different in mtDNA haplotype) was moderate, averaging 0.53 (range from 0.1 in Rabbit Key, Florida to 0.82 in New York). Between-population nucleotide divergence estimates averaged 0.46% but did not show a clear correlation with geography. Curiously, the most northern populations (NY and NJ) exhibited lower divergence relative to Florida populations (Florida Bay, Homosassa and St. Joseph's Bay) than when compared to the geographically closer North Carolina (Core and Bogue Sound) populations (Table 3). The New Jersey sample was equally distant from its adjacent population: 0.066% relative to North Carolina, 0.068% relative to New York. Haplotype frequency distributions were significantly different among surveyed populations ($\chi^2 = 250.53$, $P < 0.0001$). Pair-wise comparisons revealed a lack of significant difference between the New Jersey and North Carolina samples ($\chi^2 = 29.78$, $P = 0.168$) but highly significant differences between New Jersey and New York ($\chi^2 = 23.01$, $P < 0.0001$).

Three working hypothesis regarding population structure in bay scallop were tested using AMOVA. The greatest amount of variation was accounted for with the New Jersey sample grouped with the North Carolina samples (alternate hypotheses grouped New Jersey with New York, or as a distinct New Jersey entity), supporting the result of the analysis of the haplotype frequency distributions. The majority of the variation (59.4%) was attributed to differences among regions (regions defined as North Atlantic (NY), South Atlantic (NJ, NC) and Gulf (FL)) while only a small fraction (1.8%) of the variation was accounted for by genetic differences among samples within defined regions (Table 4).

DISCUSSION

For species of economic value, assessing population structure and reproduction is essential for both wise management of healthy populations and conservation and enhancement of endangered populations. For bay scallops in New Jersey, some information exists regarding the commercial nature of the fishery and landings from preceding decades (Ford 1997), but virtually nothing is known about the ecology of this species. One feature of bay scallop ecology that is relatively well known for many other populations is reproductive effort. Our results indicate that bay scallops in New Jersey spawn in late summer or early fall (Table 2, Fig. 2), and recruit to eelgrass habitat in October, as evidenced by collection of a few newly recruited individuals in both 1998 and 1999. However, based on the assessment of gonadal condition index (Table 2) and the maximum GSI values (Fig. 3), we believe that scallops may also show a minor late-spring spawn. Although no recruits were collected during the summer, the visual gonad condition index suggested post-spawn conditioning of bay scallops from July 1999 (Table 2). This pattern of reproduction appears to be opposite of populations from New York, which show maximum reproductive effort during May through August, with only minor contributions during the fall (Tettelbach et al. 1999). However, it is similar to the reproductive pattern of bay scallops from North Carolina, which exhibits a strong fall spawn and a much less well documented early spring event (Peterson et al. 1989).

Given that bay scallops may suffer high mortality after spawning (Marshall 1963), significant research has focused on reproduction, reproductive conditioning and changes in biomass associated with gonad development (Bricelj et al. 1987a, Bricelj et al. 1987b). It has been shown that scallops show distinct peaks in spawning activity and these peaks differ temporally based on latitude of the populations (Sastry 1970, Barber & Blake 1983, Crenshaw et al. 1991). Although scallops do show peaks in reproductive activity, recruiting individuals (< 15 mm shell height) have been reported throughout the year, suggesting that trickle spawning may occur in some locations (Gutsell 1930, Bricelj et al. 1987b, Bologna 1998). Although our data are limited in scope, we surmise that only the

fall spawn contributed significantly to the local population during this study, since no recruits or juveniles were seen during the summer. Additionally, assessment of the size frequency distribution of individuals collected in 1998 (Fig. 2) showed no discernible multiple modes in the distribution. As such, it appears that a single year cohort dominates this population, with few individuals surviving two years. Although large adults did survive the winter of 1998–99 (Table 2, May 1999)

The recent sporadic occurrence of bay scallops in the inland bays of New Jersey might be attributed to one of two scenarios. First, these pulses of adults could be traced to an occasional successful reproductive event by a small resident population. Alternatively, these ephemeral populations may represent a chance recruitment of allochthonous larvae from more stable populations located north or south of New Jersey. These scenarios have different consequences with respect to genetic composition of the New Jersey scallops. The expectation under the first hypothesis is that the New Jersey scallops would be genetically distinct from scallops collected from adjacent populations. While it is true that the New Jersey population is not likely to have been isolated for sufficient time for major genetic divergence to have occurred, the presumed frequent bottlenecking of the population suggested by the absence of detectable numbers in most years would likely have resulted in genetic drift. Under the second hypothesis of episodic recruitment from adjacent populations, the expectation is that the New Jersey scallops would genetically resemble either *A. i. irradians* to the north or *A. i. concentricus* to the south.

The results of the statistical analysis clearly support a closer relationship of the New Jersey scallops with the populations sampled in North Carolina, despite the notable genetic distance between these samples (Table 3). This association is supported by the conventional interpretation of morphological data, which originally described the southern sub-species from type specimens collected from New Jersey. The genetic differentiation between New Jersey and North Carolina may be indicative of some restriction of genetic exchange, although the data presented here are insufficient to conclude that these populations are isolated from one another. The short larval duration of *A. irradians* (10–14 days) makes the probability of direct transport of larvae from North Carolina unlikely. While scallops are occasionally found in the inland bays of Maryland and Virginia, the ephemeral nature and low densities of these populations make them poor candidates as a source for larval export. The absence of evidence to support long distance larval transport in bay scallops is not uncommon. Arnold et al. (1998) found little evidence to support significant larval transport from "high" density populations (St. Joseph's Bay and Steinhatchee) in northwest Florida to "low" density populations further to the south (Crystal River and Anclote). Other studies in the sounds of North Carolina and the Peconic Bay system in New York show a similar lack of recruitment in areas decimated by toxic algal events from adjacent unaffected areas over much smaller spatial scales (Peterson and Summerson 1992, Wenczel et al. 1993). As such, it is likely that the New Jersey population of bay scallops is a resident, albeit cryptic one.

TABLE 4.

Hierarchical analysis of variance on the matrix of distances between scallop mtDNA haplotypes.

	Observed partition			
Variance component	Variance	% Total	p	ϕ statistics
Among regions	0.00553	59.42	<0.001	$\phi_{ct} = 0.549$
Among populations within regions	0.00017	1.79	0.022	$\phi_{sc} = 0.044$
Within populations	0.00361	38.79	<0.001	$\phi_{st} = 0.612$

Population samples were grouped into three regions (New York; New Jersey and North Carolina; Florida). ϕ statistics measure haplotypic correlations and are analogous to the hierarchical *F*-statistics of Cockerham (1969, 1973). *P* values indicate the probability of finding a more extreme variance component and ϕ-statistic than that observed by chance alone.

Assessment of recruitment habitat provided novel insight into the ecology of New Jersey bay scallops. During 1998, juvenile bay scallops were observed in the field during October. While this event alone was not unexpected, the fact that the two recruiting juveniles (shell height 6 and 12 mm) were both attached to adults via byssal threads is intriguing. This behavior was most likely their response to the lack of above ground eelgrass biomass (Fig. 4). This behavior has been observed for Antarctic scallops, *Adamussium colbecki* (Berkman 1988), but observations of this occurring for *A. irradians* have not been recorded. Clearly, for an organism that is so intimately tied to seagrass as primary habitat, the loss of eelgrass signaled a significant loss of recruitment habitat. The loss of eelgrass also may have played a significant role in over-winter mortality. Field collections during November 1998 indicated that substantial passive burial of adults was occurring. Specifically, adults were frequently located within a recessed pit approximately 5–8 cm deep or adjacent to one with sediment fouling apparent on the dorsal shell. Although these observations were not quantified during this period, they suggest that sediment burial was occurring and may have had significant impacts on winter survival. Tettelbach et al. (1990) showed significant winter mortality due to burial for bay scallops in New York, and our observations of burial in 1998 and lack of adults in 1999 correspond to this trend.

Eelgrass not only serves as a primary recruitment habitat for bay scallops, but the beds also alter water velocity, dampen wave energy, and stabilize sediments (Fonseca et al. 1982, Fonseca & Fisher 1986). Consequently, the loss of eelgrass during the summer and fall of 1998 (Fig. 4) may have had direct effects on the abundance of settling bay scallops and also indirect effects on the population, in that the lack of sediment stability may have led to increased winter mortality through burial. These losses in eelgrass biomass correspond to the reduction in bay scallop population density during 1999 (Table 1), but not their elimination from the system.

Since the turn of the century, seagrasses have undergone dramatic declines worldwide due to both natural and anthropogenic sources (Phillips 1982, Cambridge et al. 1986, Robblee et al. 1991). Over the last 25 years, several studies have investigated the distribution of seagrass from coastal New Jersey and have shown significant declines in total coverage (R. Lathrop pers. comm., Bologna unpubl. data). These declines parallel the loss of the commercial and recreational fishery for bay scallops in New Jersey as well (Ford 1997). If continued loss of *Zostera marina* habitat occurs, it may severely limit this population in the future.

ACKNOWLEDGMENTS

We would like to thank E. Duval, D. Craige, and S. Piotrowski for assistance in the laboratory and field. Genetic analysis was facilitated by the efforts of T. Jones and S. Campbell. Samples for genetic analysis were provided by W. Arnold (FL), C. Lund (FL), S. Tettelbach (NY) and T. Murphey (NC). P. Bowers provided the base map of seagrass coverage in Figure 1. Financial support for this project was provided through the Rutgers University Institute of Marine and Coastal Sciences (IMCS) and the Rutgers University Marine Field Station. This is IMCS contribution No. 2001–10.

EFFECT OF MICROALGAE PROTEIN ON THE GONAD DEVELOPMENT AND PHYSIOLOGICAL PARAMETERS FOR THE SCALLOP *ARGOPECTEN PURPURATUS* (LAMARCK, 1819)

ANA FARÍAS* AND IKER URIARTE

Instituto de Acuicultura, Universidad Austral de Chile, Casilla 1327, Puerto Montt, Chile

ABSTRACT We scanned the effects of food quality on gonadal development and physiological parameters (feeding rate, absorption efficiency, oxygen consumption rate, and excretion rate) for the Chilean scallop, *Argopecten purpuratus*. Scallops were fed microalgal diets with three different protein levels, named low (L), normal (N) and high protein (H), or subjected to starvation (C). In addition, scallops were conditioned to environmental temperature in every season of the year and in the winter two temperatures were tested (field temperature of 10 C and 15 C). The gonads of the groups receiving the normal and high protein diets matured during the conditioning experiments and responded to spawning stimuli. The gonads of scallops fed on the low protein diet did not ripen and could not be stimulated to spawn at the end of the experiments. A maximum fecundity rate and massive spawning, when subjected to spawning stimuli, was obtained in scallops fed a high protein diet in the autumn experiment. Scallops fed a high protein diet increased filtration rate, absorption efficiency, and showed highest scope for growth (SFG) and net reproductive efficiency (K2) values. Medium values of filtration rate, absorption efficiency, SFG and K2 were observed in the scallops fed on a normal protein diet. Scallops fed on a low protein diet had the highest oxygen consumption, lowest filtration rate, decreased absorption efficiency and negative SFG and K2 values. Considering that the low protein diet was rich in carbohydrates, the imbalance of low protein to energy (P/E) could have caused poor protein synthesis when fulfilling energy demands resulting in reduced gonadal growth. However, the poor physiological condition of scallops fed the low protein diet was still better than for starved scallops. The positive SFG observed in the winter at 15 C with the high protein diet showed that the Chilean scallop could be conditioned in the winter by both increased temperature and dietary protein. We propose that physiological responses through reproductive conditioning of the Chilean scallop may be modulated by the protein content of the diet and by the relation P/E of the microalgae. In addition, the increase of protein level of the microalgae improves the SFG and fecundity of scallop broodstock.

KEY WORDS: *Argopecten purpuratus*, mollusc nutrition, physiology, protein requirement, reproduction, scallop

INTRODUCTION

The Chilean scallop, *Argopecten purpuratus*, is being cultured in experimental and commercial hatcheries in the north and south of Chile; and most often larvae are obtained from induced spawning of long-line cultivated adult scallops, without laboratory conditioning (DiSalvo et al. 1984, Uriarte et al. 1996a). Martínez et al. (1999a) provided some data on the physiological aspects of maturation and the importance of nutrition during gonadal development which has been studied by Coutteau et al. (1996), Farías et al. (1997), Marrit et al. (1999), Martínez et al. (1999b).

The biochemical composition of microalgal cells can be varied by altering the nitrogen concentration of the culture medium (Wikfors et al. 1984, Utting 1986, Uriarte et al. 1993). The biochemical modification of the microalgal cultures is an important tool not only for research on the nutritional requirements of filtering organisms, but also for determining the efficient use of microalgae during phases of high consumption for the postlarvae stage and during reproductive conditioning (Uriarte & Farías 1999). Utting (1986) found that oyster larvae grew better when fed carbohydrate-enriched microalgae, while oyster spat grew better on protein-enriched microalgae. Farías et al. (1997) found that the fecundity of adult scallops increases when fed protein-enriched microalgae. Thus, alteration of the nutritional media could be an effective way to control the biochemical quality of microalgae and improve efficiency of production by hatchery (Uriarte & Farías 1995, 1999).

The present study evaluates the effect of biochemically manipulated microalgae on the physiology and gonad development of adult *Argopecten purpuratus* which were introduced in the south of Chile where no natural populations exist.

MATERIALS AND METHODS

Microalgae of Different Protein Level

We manipulated cultures of *Isochrysis aff. galbana* (clon T-Iso) and *Chaetoceros neogracile*, using the method described by Uriarte et al. (1993) with the modifications of Uriarte & Farías (1999). Three strains pre-conditioned for two years at the different nitrogen levels (high protein, normal protein and low protein) were selected for the bulk production of algae for our experiment on the reproductive conditioning of *Argopecten purpuratus*. As all the cultures were grown using the same light, temperature and aeration conditions, the nitrogen content in the media was the only factor that varied. The microalgae of each species were harvested daily during their exponential growth phase. Three diet treatments were prepared by a mixture of both species in a proportion 1:1 for each protein level: high protein, normal protein and low protein. A fourth treatment was, starving of scallops during the entire conditioning period.

Conditioning Experiments

The scallops were collected from the long-line of the Laboratorio Biológico Pesquero de Putemún (IFOP, Region X, 42°25′S). The scallops were 22 to 30 months old.

The experiments were run during five periods: spring 1995, autumn 1996, winter 1996, spring 1997, summer 1997, at temperatures of 15, 13, 10, 16, and 15°C respectively, corresponding to the average field temperatures.

Scallops were measured, weighed and induced to spawn just before each experiment. Gonad maturation was assessed using a visual index (Mason 1983). During the eight weeks of the experiment, one scallop per tank of 8 L was suspended in recirculated

and filtered (0.5 μm) seawater. The exceptions were the first and last experiment both during springtime, where tanks of 250 L with 15 tagged scallops were employed. In each test, the water was changed and the tanks and tubes cleaned every second day.

The spring 1995 experiment was aimed to detect changes in the biochemical composition of scallop tissues and to determine the optimal food ration for reproductive conditioning. Scallops were fed with two diets: low protein (L) and normal protein (N). There was one tank of 250 L per diet, each tagged scallop in the suspended sieve was considered a pseudoreplicate.

The autumn 1996 experiment examined the effect of three diets and starvation. There were three tanks for each treatment randomly distributed. The diets had three different qualities of microalgae: high (H), low (L) and normal (N) protein level.

The winter 1996 experiment took place when the field temperature was 10°C and the study aimed at the combined effect of temperature and diet. Two temperatures were tested: 10 and 15°C in combination with high and normal protein diets and starvation, keeping three replicates randomly distributed, for each diet/temperature combination.

The spring 1997 experiment evaluated the effect of high and normal protein diets, the pseudoreplicates were 15 tagged scallops for each diet suspended in a sieve inside of 250 L tank with recirculated water.

The summer 1997 experiment evaluated the effect of high, low and normal protein diets, with three tanks for each treatment, randomly distributed.

The microalgal diets were continually delivered to the broodstock with a peristaltic pump. The daily rations were based on the results of the spring 1995 experiment.

Biochemical Analysis

At the end of the first experiment, we made biochemical analyses of gonad, digestive gland and muscle of scallops, as these body components are likely sites of energy storage for subsequent use in gonad maturation (Martínez 1991, Uriarte et al. 1996b).

During the conditioning period of the autumn experiment the biochemical analysis of each microalgae species and quality was run. Samples of known concentration and volume of microalgae were filtered on pre-ashed and pre-weighed Whatman GF/C filters using a vacuum system (pressure less than 5 in. Hg). The filters were dried to constant weight at 40°C and subsequently frozen at −20°C until analyzed. The biochemical characterization of the various mixtures of microalgae was estimated from biochemical data on individual microalgal species.

The biochemical analysis were carried out using the methods cited by Farías et al. (1998) using bovine gamma-globulin, cholesterol and glycogen of oyster as standards for protein, lipid and carbohydrate, respectively. The energetic content of the diet was calculated based on the energetic equivalents for protein, lipid and carbohydrates of 23.5, 39.37 and 17.08 J mg^{-1}, respectively, reported by Paine (1971).

Physiological Analysis

Toward the end of each conditioning period, physiological evaluations were carried out on the scallops. To determine the clearance rate (CR) a closed system was used (Widdows 1985). Each experimental scallop was placed in a 1-L glass beaker, highly aerated and with an initial concentration of 10 algae-cells μl^{-1}. The reduction in particle concentration was measured in samples of 10 ml every 15 min for 1 h. An additional container with the same characteristics but with no scallop served as the control. The particles were counted after centrifugation and removal of 9.5 ml of supernatant. The experimental scallops were left undisturbed for at least 24 h before the clearance rate measurements started. CR (l h^{-1}) was calculated by the exponential regression:

$$C_t = C_0 \times e^{(-(m n M)+a)\times t}$$

where C_t is algae concentration after time t. C_0 is initial cell concentration, m is filtering rate of a single animal, n is number of scallops, M is volume of suspension, a = rate at which particles settle out of suspension in the control beaker, calculated from:

$$C'_t = C'_0 \times e^{-at}$$

The ingestion rate was estimated as the product of the clearance rate (l h^{-1}) and the cell concentration (mg L^{-1}). The feeding rate (FR) was estimated as the product of the ingestion rate (mg h^{-1}) and the energy of microalgae mixture (J mg^{-1}). The absorption efficiency (AE) was measured for each individual using the method found in Conover (1966), on the basis of fecal organic content and of food consumed during the previous 8 h. The absorption rate (AR) was estimated as the product of the feeding rate (J mg^{-1}) and absorption efficiency. The rates of oxygen consumption (VO_2) were measured at the experimental temperature in a 1.5-L closed chamber with a Strathkelvin Polarographic electrode following the methodology of Widdows (1985). The rates of ammonium excretion (VNH_4-N) were determined with the method described by Widdows (1985). Scope for growth (SFG) and net growth efficiency (K2) are reference values for the production of somatic and/or reproductive tissue, depending on the age of the bivalve (Vahl 1981). In this case the scallops were adults subjected to a conditioning regime, then the production was considered only as growth of the gonad tissue. For this reason was used the terms scope for reproductive growth for SFG and net reproductive efficiency for K2. The scope for reproductive growth (SFG), the net reproductive efficiency (K2), and the stress index (O/N ratio) were calculated by incorporating all previous physiological measurements as described by Widdows (1985). At the end of the physiological evaluation, all scallops were weighed and induced to spawn.

At the end of each experiment the body components were separated and dried at 100°C for 72 h prior to weighing. All physiological determinations were then standardized to a mean dry body mass of 4 g (close to an average scallop, 4.06 ± 0.48 g), using the equation of Bayne et al. (1993) and the regression coefficients for filtration rate, oxygen uptake, and excretion rate of Navarro and González (1998) at salinity of 30 g L^{-1}.

Statistical Analysis

The protein and energy content of the diets were compared between the two microalgae species and nitrogen levels using an ANOVA. The diet quality was characterized by the ratio protein/energy (P/E, both measured in Joules) and the total food energy availability per scallop (FE). The physiological rates and the spawning response between treatments were compared statistically using ANOVAs (Sokal & Rohlf 1981). The absorption efficiency values were arcsine transformed, because they were ratios, in accordance with Sokal and Rohlf (1981). Correlation and multiple linear regressions analyses were carried out following $\log_{10}$ transformation of the physiological rates, to reduce the dependence of the sample variance on the mean and to normalize the distribution

of the data (Navarro and Thompson 1996). The variables included in the analyses were temperature, diet quality, FE (J h^{-1}) and protein absorbed (J h^{-1}). Protein absorbed (PA) was estimated as the product of the energy absorbed (J h^{-1}) and the percentage of protein content for each diet quality. Average data were expressed as mean ± standard error.

RESULTS

Manipulated Microalgae

The protein content of the microalgae was significantly different between the qualities generated. *C. neogracile* showed a higher protein content than T-*Isochrysis* whereas the various quality cultures showed a decreasing protein content (F_{spp} = 11.53, d.f.= 1;18, p = 0.005; F_N = 30.82, d.f. = 2; 18, p < 0.0001) as follows: H > N > L (p = 0.05). The energetic contents showed that there were no significant differences between the microalgal species used. The mixture of both microalgae (Table 1) was characterized by significant differences on the protein content (F = 35.18, d.f. = 2, 7, p = 0.001), carbohydrate content (F = 36.73, d.f. = 2, 7, p = 0.001) and ratio P/E (F = 15.56, d.f. = 2, 7, p = 0.007) between qualities. The total energy, dry mass and organic matter of mixtures were similar for the three levels of protein, with averages values of: 0.94 ± 0.04 J per million cells, 44.5 ± 5.9 µg per million cells and 67.3 ± 4.0%, respectively.

Scallop Conditioning

During the spring 1995 experiment, a daily ration of 2.5 × 10^9 cells day^{-1} $scallop^{-1}$ of both the low or normal protein diets was sufficient to stimulate the ripening of gonads without producing pseudofeces. Therefore, this ration value was used as constant for subsequent experiments. The absorption efficiency values did not differ significantly between diets (Table 2), the mean absorption efficiency being 57.33% (±2.16). The Mason Index did not show significant difference in the appearance of gonads between diets. The scallops fed on the L diet had a lower gonad index.

Protein levels of scallop tissues did not differ between diets after conditioning (Table 3). However the differences were significant between tissues: 14.3 ± 2.5, 79.9 ± 3.4 and 90.3 ± 3.4% of dry weight of digestive gland, gonad and muscle, respectively. Lipid values of scallop tissues varied significantly between diets (Table 3), with maximum values for diet L (15.6% ± 1.27 of dry weight). Lipid levels between tissues were significantly different (p = 0.05) (Table 3), with the highest value for the gonad (17.6% ± 1.6 of dry weight) followed by the muscle (12.5%) and digestive gland (9.8%). The carbohydrate levels did not show differences between diets. The values varied significantly between tissues (Table 3), with low values in gonads and muscles (3.5 and 2.4% of dry weight, respectively) and a high level in the digestive gland (26.8% ± 0.9 of dry weight). Thus, only tissue lipids varied between diets.

In the autumn experiment, the clearance rate differed significantly between treatments (Table 4, F = 53.47; d.f. = 3, 8; p = 0.001). The lowest rate was observed in the starved scallops, the highest rate in the scallops fed on the H diet and there were no significant differences between the N and L diets. Oxygen uptake (Table 4) showed no significant difference between treatments. The mean VO_2 was 2.50 ml O_2 h^{-1} (±0.29), with a maximum rate (p = 0.06) seen in the scallops receiving diet L and a minimum observed in scallops fed on the N diet. The VNH_4 – N (Table 4) did not show significant differences between treatments although the highest value was observed in the starved scallops. The mean excretion rate was 193.58 (±26.46) mg NH_4-N h^{-1}. Absorption efficiency values was significantly different between diets (Table 5, F = 9.91; d.f. = 2, 17; p = 0.002), with the highest efficiency in the diet H (66.4%). No significant differences were observed between the diets N and L. The starved scallops did not show a positive absorption. Scope for growth (SFG) was significantly higher in the broodstock maintained on the N and H diets (Table 5), (F = 14.44, d.f. = 3, 8; p = 0.007), making available 23.2 and 141.3 J h^{-1} of energy, respectively, for the production of new tissues and gametes. The starved scallops and those fed the diet L showed negative SFG. Net growth efficiency (K2) was 58% in diet N, and 72% in diet H. The negative values indicated that the starved scallops and the ones maintained on diet L did not produce new tissues (Table 5), F = 16.58; d.f. = 3, 8; p = 0.005). The O/N ratio did not show significant differences between diets, although the higher values for O/N, that it means less stress, were observed with low protein diet associated to high VO_2. When induced, the scallops fed on the N and H diets spawned completely, whereas the diet L scallops were observed to release sperm only. The mean fertility was 2.8 × 10^6 (±1.1 × 10^6) eggs $scallop^{-1}$

H, L and N refers to high, low and normal protein algae, respectively. C refers to the treatment of starvation.

for diet N and 13×10^6 ($\pm 0.5 \times 10^6$) eggs scallop^{-1} for diet H. Egg diameter was 61.3 mm (±0.4) with no significant differences between the treatments. The eggs were viable and developed into scallop embryos.

There were no significant differences in clearance rate between temperatures or between diets during the winter experiment. Higher clearance rate values were characteristic for the H diets at both temperatures. The lowest clearance rate was observed in the starved scallops. Oxygen uptake did not present significant differences between temperatures but there was a significant effect between the diet (Table 4, $F_{diet} = 5.52$, d.f. = 2,11; $p = 0.04$). The minimum value for VO_2 was observed in the starved scallops. The results of VNH_4-N showed no significant difference between temperatures or diets and had a mean value of 237.84 (±57.61) mg NH_4-N h^{-1} (Table 4). Absorption efficiency values was also not affected by temperature and diet, ranging from 34.8% in diet N at 10°C to 48.2% in diet H at 15°C (Table 7). The starved scallops did not show absorption. The calculated SFG and K2 did not differ between temperatures and diets (Table 5). Higher values were observed for diet H. The highest value of SFG and K2 were observed with diet H at 10°C. The scallops fed on N and H diets at 15°C spawned when induced, whereas the scallops at 10°C did not release sperm or eggs. The eggs obtained at 15 C appeared coagulated and were not viable.

In the summer 1997 experiment, values of clearance rate did not differ between treatments (Table 4), although clearance rate was lowest in the L diet. There were no significant differences in VO_2 between the diets (Table 4). The tendency of Oxygen uptake was the same as in the above experiments, with maximum values for the scallops fed on diet L. Results of VNH_4-N indicated no significant differences between diets in spite of apparently low value for the L diet (Table 4). Absorption efficiency values were the lowest during the study and did not vary with the diet (Table 5). SFG did not differ between the treatments (Table 5) and was negative for all diets with values as low as −24.6 J h^{-1} (L diet). K2 as well was negative (Table 5), ranging between −1.6 and −1.1 for scallops fed on diets L and H, respectively. The O/N stress index tended to higher values with a low protein diet, showing a less stress condition of scallops, however only the scallops fed on N and H diets responded to the spawning induction. Scallops fed on the diet L did not release sperm or eggs and died 24 h from the effects of stimulating to spawn.

In springtime, the last experiment of 1997 revealed no significant differences for clearance rate between treatments (Table 4), although the highest value was observed for diet H. VO_2 was similar between the diets (Table 4). Excretion rate in *A. purpuratus* did not differ between diets N and H. The mean value of VNH_4-N was 504.72 (±38.87) µg NH4-N h^{-1} (Table 4). Absorption efficiency values were not affected by the diets N and H (Table 5) and had a mean value of 52.7 (±3.5) percent. SFG was negative for both diets (Table 5) with a mean value of −54.6 J h^{-1} and no significant difference between treatments. Similarly, K2 was negative (Table 5) in both diets and was associated with a low clearance rate and a high oxygen uptake. The diets had a similar O/N ratio with a mean value of 7.6 (±0.94) (Table 5). During the spawning induction, the scallops did not respond to the stimuli and died after 24 h.

Integrated Results

Clearance rates showed significant differences between seasons ($F_{season} = 8.735$; d.f. = 3,48; $p = 0.0001$) with a minimum clearance rate of 1.61 l h^{-1} (SE = 3.53, n = 10) during winter and a maximum clearance rate of 12.13 l h^{-1} (SE = 2.12, n = 25) during summer. There were significant differences between diets ($F_{diet} = 5.510$; d.f. = 3, 48, $p = 0.0025$). The minimum CR of 0.93 l h^{-1} (SE = 3.11, n = 4) was observed in the starved scallops while the maximum rate of 10.83 l h^{-1} (SE = 1.49, n = 21) was found in diet H. Feeding rate (FR) was positively correlated with the scallop weight, ratio protein/energy (P/E) of diet and seasonal temperature, while the correlation of FR with absorption rate and protein absorbed was attributed to the autocorrelation of these variables (Table 6). Multiple regression analysis between FR and the experimental variables accounted for 45% of the variation (Table 7). Dry mass of the scallops alone explained 20% of the variation.

Absorption efficiency varied significantly with seasons ($F_{season} = 15.69$; D.F. = 1, 153; $p = 0.00001$), with maximum values in autumn (68.25%, SE = 4.26, n = 18) and minimum values in summer (23.18%, SE = 4.26, n = 18). No significant differences were observed between the diets. The starved scallops showed a negative absorption. The overall annual mean value for absorption efficiency, independent from the diets, was 50.52% (SE = 1.77, n = 160). The absorption rate (J h^{-1}) correlated with many of the nutritive variables, and showed an especially close correlation with the energy and protein level of the diet (Table 6). Food energy availability and ratio protein/energy (P/E) explained 59% of the variation in absorption rate (Table 7).

Oxygen uptake showed significant differences between seasons ($F = 8.54$, d.f. = 3,51, $p = 0.0001$). The highest value, of 2.68 ml O_2 h^{-1} (SE = 0.27, n = 14), was in spring and the lowest, 1.30

H, L and N. C refers to the starved scallops.

ml O_2 h^{-1} (SE = 0.35, n = 12), in winter. Oxygen consumption rates tended to vary between diets (p = 0.06). Scallops receiving diet L tended to consume most oxygen (2.54 ml O_2 h^{-1}, SE = 0.28, n = 11) and the starved scallops least (1.47 ml O_2 h^{-1}, SE = 0.43, n = 4). VO_2 was positively correlated with the seasonal temperature and food energy availability (Table 6), and negatively correlated with the total food cells in the tanks (FT). The multiple regression models explained 31% of total variation in oxygen uptake (Table 7), with food energy availability accounting for 14%.

The ammonium excretion rates showed seasonal differences (F_{season} = 3.099, d.f. = 3,55, p = 0.03) with a maximum value of 478.19 mg NH_4-N h^{-1} (SE = 49.45, n = 14) in spring time and a minimum of 288.63 mg NH_4-N h^{-1} (SE = 64.27, n = 11) in autumn. The ammonium excretion rates did not vary with diets. VNH_4-N in *A. purpuratus* was highly correlated with the experimental temperature, the seasonal temperature and the food cells in the tanks (Table 6). The best multiple regression model for VNH_4-N showed that 48.5% of the variation was explained by experimental temperature, ratio protein/energy (P/E) and feeding rate, whereas experimental temperature alone accounted for 41% of the variation (Table 7).

The reproductive SFG (Fig. 1) varied between seasons (F_{season} = 26.27, d.f. = 0.3, 34, p < 0.0000001) and between diets (F_{diet} = 17.24, d.f. = 1, 34, p = 0.0002). SFG was negative during spring and summer, close to zero during winter and above zero during autumn SFG. There were significantly higher values of SFG in scallops fed on diet H. The seasonal difference was most conspicuous in starved *A. purpuratus* (Fig.2) (F_{season} = 6.86, d.f. = 1, 9, p = 0.03). The SFG was always negative, but ranging from values as low as −62.78 J h^{-1} (±17.05) in autumn to values very close to zero in winter. SFG for three N-diets plotted (Fig.3). During summer, SFG was not influenced by the diet. In contrast, SFG was affected by the diet in autumn, suggesting that there was a strong positive relationship between SFG and ratio protein/energy (P/E) in this season ($F_{season\ P/E}$ = 18.29, d.f. = 2, 26, p = 0.0000009). Scope for reproductive growth was correlated with the nutritive variables, protein absorbed and total food availability, and with two physiological variables, feeding rate (FR) and VO_2 (Table 6). Multiple regression analysis showed that 68% of the total variance of SFG was explained by protein absorbed, food availability, VO_2 and FR, whereby protein absorbed alone accounted for 23% (Table 7).

The net reproductive efficiency (K2) was highly correlated with the seasonal temperature, food energy availability, and absorption rate (Table 6). Food energy availability alone explained 33% of the variation and when the seasonal temperature, absorption rate, FR and the O/N ratio were included, 86% of the variation was explained (Table 7).

The O/N stress index was negatively correlated with the experimental temperature and food energy availability (Table 6). The variation of O/N was best explained by the model which included the seasonal and the experimental temperature, food energy availability and ratio protein/energy (P/E) as independent variables, explaining as such only 27% of the variation (Table 7).

DISCUSSION

The experiments on conditioning *A. purpuratus* showed that scallops fed on the high protein diet, had both the highest scope for reproductive growth (SFG) and net reproductive efficiency (K2) (parameters considered as indexes of success of reproductive conditioning, because the production was not detected as somatic growth but as gonadic growth), followed by the scallops conditioned on the normal protein diet. The scallops fed on the low protein diet or starved had the lowest SFG and K2 values.

Number of cases in parentheses. FR: feeding absorption rate; VO_2 oxygen consumption rate; VN-NH_4: ammonia excretion rate; SFG: scope for growth; K_2: net growth efficiency; O/N: stress index; Season: seasonal; ExpT: experimental temperature; DWT: scallop dry weight; P/E: quality diet index; PA: protein absorbed; FE: food energy availability per scallop; FT: total food cells in the tanks; cells availability per scallop.

The clearance rate ($l\ h^{-1}$) and the absorption efficiency values followed the same pattern as described in the preceding paragraph, highest values on diet H, medium on diet N and the lowest values in the scallops fed on diet L. Our results suggest that improvement of reproductive conditioning on *A. purpuratus* is the product of the combined effect of high clearance rate and increased absorption efficiency values. The same pattern to maximize the net energy in bivalves when food quality increases is described by Navarro et al. (1994).

The respiration rates (VO_2) did not follow the same pattern of SFG or K2 in relation to the protein content of the diets. The lowest respiration rates were for the scallops fed a normal protein diet, and reflected their low level of activity compared to the scallops in the other treatments. Shumway et al. (1988) found that metabolic rate is simultaneously affected by food, temperature and reproductive stage, and state that it is difficult to separate these effects without a good knowledge of how energy is allocated between somatic growth and gametogenesis. We observed an unexpectedly high VO_2 in the non-fed group in autumn, which might have been caused by the food particles consumed during the clearance rate test the previous day. However, the feeding activity did not provoke an increase in oxygen consumption in other pectinid genera such as *Chlamys*, although an increase was observed in mytilids (Mackay & Shumway 1980).

Excretion rates were not affected by dietary protein levels, contrary to the findings of Hawkins and Bayne (1991). Scallops required more proteins than mussels as previously reported in studies in *Argopecten irradians* by Barber and Blake, (1985) and Epp et al. (1988). The level of energy in the high protein diet (where we

expected a maximum VNH_4-N) could have been enough to use the available protein, producing more gametes and reducing losses due to NH_4-excretion The high VNH_4 observed in the starved scallops suggest the use of protein to meet metabolic demands during prolonged starvation as previously documented in mussels and in the scallop *Argopecten irradians* (Epp et al. 1988, Hawkins & Bayne 1991).

The similarity in egg size for scallops fed high and normal protein diets indicated that the additional protein in the high protein diet is mainly used for the production of a larger number of eggs and not for larger eggs. A similar strategy has been observed for *Placopecten magellanicus*. Scallops found in poor environmental conditions had a reduced fecundity but the quality of the eggs was maintained (Thompson & MacDonald 1990, Napolitano et al. 1992).

The maintenance costs of scallops with a low protein diet exceeded the energy assimilated. Diet L scallops had lower clearance rate and absorption efficiency, as well as a high tendency to form

pseudofeces and higher oxygen uptake. The reduction in clearance rate and absorption efficiency values together with pseudofeces production are feeding responses of bivalves predicted by Navarro et al. (1994) when food quality is poor. We observed a tendency to increase oxygen consumption during oogenesis of *Argopecten irradians* indicating metabolic use of carbohydrate (Barber & Blake, 1985) and in our study could be related to a high degradation of dietary carbohydrates. On the other hand a maximum lipid value observed in the tissues of scallops fed diet L, was not related to the lower gonad index in the same scallops, but could be indicated that a carbohydrate excess of this diet was being converted to lipids which are presumably stored in developing ova. Considering that diet L was very rich in carbohydrates and showed the lowest protein content and the lowest ratio protein/energy (P/E) index, it could have caused a dietary imbalance such as documented for fish, characterized by an excess of dietary energy associated with a decreased protein intake, poor protein synthesis and reduced growth (Young Cho 1987, Tacon 1990). However, the physiological condition of the diet L scallops was still better than that of the starved scallops, and they may be diagnosed as undernourished scallops.

Massive spawnings in the diets H and N were only observed in the autumn. In the other seasons, the gonads were ripe but could not be stimulated to spawn and this was associated with a negative SFG. We propose that the microalgal requirements varied seasonally and 2.5×10^9 cell day^{-1} $scallop^{-1}$ was enough to develop gametes in spring 1995, autumn 1996 and winter 1996, but did not meet energy requirements to mature or to spawn in the other seasons or when diet L was applied. Loss of the relationship between SFG and diet quality in summer could be attributed to insufficient food. This was suggested by the mortality after stress from spawning induction. The negative SFG observed in spring 1997 could have been caused by the change in the culture system. The movement of the scallops was more restricted and they decreased their consumption rate. The mortality after induction of spawning in this experiment was likely associated with the increased requirements to fuel the sudden increase in gonad growth. The positive SFG observed in winter 1996 at 15°C with diet H showed that the Chilean scallop could be conditioned over the winter by increasing temperature and dietary protein level.

The net reproductive efficiency (K2) was the parameter most related to seasonal temperature and its intense effect on VO_2. The

O/N ratio (stress index) was lower than that reported for the Chilean scallop by Navarro and González (1998) and this may be related with the higher reproductive activity of the scallops in our study. The low values of O/N index associated with high excretion rates of reproductive scallops mean that gametogenesis in scallops occurs mainly at the expense of the adductor muscle protein as suggested by Barber and Blake (1985) and Epp et al. (1988).

Low temperature or low energy availability might have caused high stress condition in reproductive adult broodstock conditioned at 10°C in the winter experiment. Similarly, scallops from the field in southern Chile at the end of winter, experienced massive mortalities when they were ripe (Farías et al. 2001). The Chilean scallops in our study are below their normal distributional limit (35° S) and represent second generation individuals originating from broodstock from northern Chile (Region IV, 30°16′S) (Uriarte et al. 1996a). We propose that southern *A. purpuratus* and some populations of *A. irradians* could be nutritionally and climatically stressed, (Barber & Blake 1985) since available food and glycogen reserves are insufficient to support reproduction and maintenance metabolism. In addition, the catastrophic mortalities observed at southern Chile, could be associated with the three main factors that affect the seasonal metabolism of adult scallops (Shumway et al. 1988, Uriarte et al. 1996 b): stress caused by low temperature (<10°C), low food availability, and high energetic demand for gonad ripening.

Martínez et al. (1999 b), showed that microalgae enriched with a mixture of lipids improved the conditioning of *A. purpuratus*. Uriarte and Farías (1995, 1999) have shown that protein content of the microalgal diet affect the physiology and growth of juvenile scallops up to a size of 2 mm, and after this other dietary factors are probably more important. The present work confirms the importance of increasing protein in microalgae to improve the efficiency of massive production in the hatchery. The diet H influenced the SFG and the gonadic growth of scallop *A. purpuratus* by the increase of clearance rate, absorption efficiency values and the improvement of the relationship between oxygen uptake and ammonia excretion. The interaction between dietary protein and lipid enrichment on gonad ripening would be an interesting task for future investigation.

ACKOWLEDGMENTS

This work was supported by the International Foundation for Science (IFS A-2074 of the first author) and FONDECYT (grant 1970807 of the second author). We thank P. Varas, S. Pino, J. Gallardo and J. Santana for their assistance in the laboratory work. We also acknowledge useful corrections and comments by S. Utting (England) and N. Nevejan (Belgium). Special thanks to programa Acuicultura y Biotecnología Marina, I (97), FONDAP, Chile (Subprograma Invertebrados) for the valuable discussion on the topics of this manuscript.

STEPHANOSTOMUM SP. (TREMATODA: ACANTHOCOLPIDAE), THE CAUSE OF "PIMIENTILLA" DISEASE IN CATARINA SCALLOP *ARGOPECTEN VENTRICOSUS (CIRCULARIS)* (SOWERBY II, 1842) IN BAJA CALIFORNIA SUR, MÉXICO

JUAN C. PÉREZ-URBIOLA[1] AND SERGIO F. MARTÍNEZ-DÍAZ[2]

[1]Centro de Investigaciones Biologicas del Noroeste, La Paz, Baja California Sur, Apdo. Postal 128 CP 23000, México; [2]Centro Interdisciplinario de Ciencias Marinas, Playa Conchalito S/N La Paz, Baja California Sur, CP 23000, México

ABSTRACT We investigated the etiology of a disease of catarina scallop (*Argopecten ventricosus (circularis)*) during an outbreak in Baja California Sur, B.C.S., México, in the summer of 1995. Samples from Bahía Magdalena and Bahía Concepción were studied. Our results indicate that the disease named "pimientilla" is caused by encysted metacercaria of the trematode *Stephanostomum* sp. The melanized spots in the adductor muscle characteristic of the disease are cysts of this trematode. Almost all scallops analyzed had abundant cysts. The characteristics of the matacercariae are described and compared with that of other species of *Stephanostomum*.

KEY WORDS: *Stephanostomum*, metacercaria, catarina scallop, disease

In Baja California Sur (B.C.S.), México, the catarina scallop (*Argopecten ventricosus (circularis)*) fishery is an important economic activity employing about 7,000 families in extracting, processing, and marketing. The production of catarina scallop was 7,000 t of adductor muscle during 1989 and 1990, with more than 4,500 t in 1989 from Bahía Magdalena and Bahía Concepcion (Massó 1996).

In recent years, the catarina scallop fishery has been affected by the collapse of natural stocks and by the presence of some parasites, which caused a decrease in production volumes. During 1978 and 1992 the fishing areas of La Paz and Bahía Concepción, respectively (Fig. 1) suffered a collapse of their natural stocks. Such events were associated with overfishing in La Paz (Baqueiro et al. 1981) and with adverse environmental conditions in Bahía Concepción (Massó 1996). During 1978, the commercial fisheries in Lagunas Guerrero Negro and Ojo de Liebre B.C.S. were closed temporarily by the Mexican Health Ministry. This was necessary because an outbreak of nematodes (*Echinocephalus pseudouncinatus* in the adductor muscle) was detected, which required an evaluation of their effect on human health (Gómez del Prado 1984). Later studies showed the presence of metacercariae and metacestodes of the families Fellodistomidae and Phyllobothriidae in the adductor muscle, and metacestodes of Trypanorhyncha in gonads and hepatopancreas (Gomez del Prado et al. 1992). Massó (1996) concluded that there was no risk to human health.

In pectinids, some parasites cause massive infections and mortality in natural populations (Moyer et al. 1993, Whyte et al. 1994), and consequently cause significant economic losses to fisheries and mariculture by a decrease in the catch volumes and by the reduction in yields and quality as human food.

During summer 1995 (June and July), an outbreak of disease was detected in the commercial stocks of catarina scallop in B.C.S. The main sign of disease was the presence of abundant melanized spots in the adductor muscle, which resembled pepper granules (Fig 2a). Attempts to determine the aethiologic agent using standard histological techniques failed. The objective of this study was to determine the etiology of the "pimientilla" disease and ascertain if the disease represented a risk to human health.

To determine the cause of the disease, 450 specimens were submitted to the Department of Experimental Biology of the Interdisciplinary Center of Marine Sciences in July and August 1995. The specimens were collected in the two main areas of commercial exploitation of B.C.S.: Bahía Magdalena on the Pacific Coast and Bahía Concepcion on the Sea of Cortéz (Fig. 1). After collection, the specimens were kept on ice before analysis.

In the laboratory, the spots were dissected from the adductor muscle. The parasites were extracted by pressing spots between two glass slides and were fixed in AFA (70% ethanol:Formalin:Acetic acid, 80:10:10). Specimens were stored in 70% ethanol, stained with Gomori Trichromic, and mounted in synthetic resin. The description of the aethiological agent was based on nine mounted organisms. Measurements were made with an ocular micrometer.

There was a high prevalence of diseased scallops from both sites. Ninety-eight percent of specimens analyzed show the characteristic signs of disease (small brownish spots in the adductor muscle). The spots in the muscle were caused by the presence of embedded cysts. The number of cysts per adductor muscle varied between a few to more than 800. From each cyst, we recovered a metacercaria, which was identified as *Stephanostomum* sp.

The characteristics of the metacercariae (Fig. 2b) recovered were: body 764 μm (554–1291 μm) long and 280 μm (228–316 μm) width, tegumental spines, terminal oral sucker of 241 μm (208–292 μm) long and 235 μm (180–361 μm) with the mouth located in the mid-region of the body, and two rows of 28 oral spines each (56 total) 43 μm (36–56 μm) long and 18 μm (12–21 μm) width. The prepharynx was 234 μm (50–476 μm) long and the pharynx 132 μm (98–157 μm) long and 122 μm (92–146 μm) width, continuing posteriorly to the intestinal bifurcation, that is in the posterior forebody. The caecae reach close to posterior extremity and end blindly.

The ventral sucker is preequatorial with diameter of 264 μm (201–362 μm). There are a pair of dorsal ocelli between the oral sucker and the pharynx. There are reproductive organs in immature stage in the posterior third of the body, and two testes in line, the ovary is located anterior to the testes. The genital pore is just

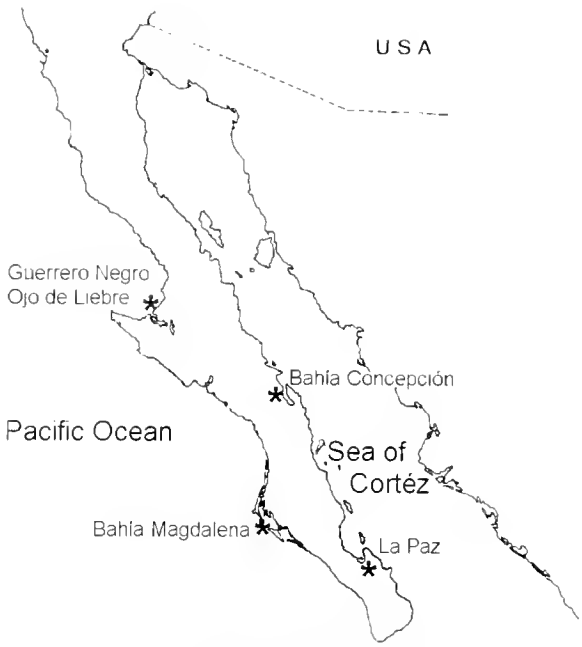

Figure 1. Catarina scallop *Argopecten ventricosus (circularis)* sampled areas.

before the body middle line and the excretory vesicle in I-like form.

The genus *Stephanostomum* includes numerous parasites of marine teleosts, generally warm-water species (Quinteiro et al. 1993). Species determination in adult stages is based on morphological characteristics, e.g., the number, shape, and position of peristomial spines, the relative size of the oral and ventral suckers, the number and distribution of vitellaria, the size of the cirrus sac and the genital atrium, the distance between gonads, the presence or absence of uroproct, and the egg size (Stunkard 1961).

In the metacercariae recovered from catarina scallop, the abundance of cephalic spines (56) is similar to that of *S. pronicropsi* (50–58), *S. baccatum* (56–60), and *S. fistulariae* (56). However, *S. pronicropsi* has been reported only from the North Atlantic and although *S. baccatum* has been reported in the Pacific Ocean of North America, the metacercariae has only been reported in sole (Table 1). *S. fistularinae* has only been reported from Japan, and the life cycle has not been described yet. The number of cephalic spines in the 13 species of *Stephanostomum* found in the Pacific Ocean of North America (Love and Moser 1983) do not coincide with the metacercariae found in the catarina scallop. The results obtained in the present study indicate that the specimens recovered from catarina scallop have unique characteristics. Although there is not sufficient information available for the complete identification at species level, we can't discard the possibility of it being a new species.

The complete cycle of *Stephanostomum* comprises three principal stages: redia, metacercaria, and adult, all of which require different hosts. Most species of the genus have been described from adult specimens, and intermediate hosts are unknown (Table 1 shows the species for which the intermediate hosts are known). The complete cycle is known for *Stephanostomum tenue* and *Stephanostomum baccatum* and the metacercaria, and adults of *Stephanostomum japonicum*, *Stephanostomum bicoronatum*, *Stephanostomum hispidum*, *Stephanostomum carangium*, and *Stephanostomum lophii* have been described as parasites of fish (Table 1). In general, the rediae of *Stephanostomum* are parasites of gastropods and the other stages are parasites of marine fish. This is the first record of a bivalve mollusk that acts as an intermediate host for *Stephanostomum*.

Catarina scallops inhabit sandy bottoms, coexisting with some gastropods, and is preyed upon by fish. To date in B.C.S., gastropods have not been reported as hosts of rediae of *Stephanostomum* nor have fish been reported as a definitive host. However, the species *S. californicum* and *S. dentatum* have been reported in La Jolla, California from the intestinal tract of the yellowfin croaker (*Umbrina roncador*) and the California halibut (*Paralictis californicus*), respectively (Manter and Van Cleave 1951). Nevertheless, the number of cephalic spines in the adults of these two species does not match the number on the metacercaria from catarina scallops.

No metacercariae were found alive during the dissection. The method employed for transporting the scallops during our analysis is similar to that used commercially, suggesting that the parasite would not survive during commercial processing and shipping. Furthermore, the life cycle of this parasite does not include mammals. Thus, we can discard concerns for human health. However, a bigger problem is the decrease in the quality of the market product. Because when the infestation is severe, the product will not meet the standards of quality required for international commercialization.

The catarina fishery is an important economic activity in Baja California Sur. The recent collapse of natural stocks has been

associated with overfishing and adverse environmental conditions. Consequently, the cultivation of this species is gaining importance (Castro-Ortíz 1993). During our study, we found a high prevalence of infected scallops and a high intensity of cysts embedded in the adductor muscle. Further research is necessary to determine the effect of *Stephanostomum* outbreaks on natural and cultured populations and the risks that this parasite may impose on scallop culture.

INFLUENCE OF THE GONADAL CYCLE AND FOOD AVAILABILITY ON POSTMORTEM CHANGES IN GLYCOGEN, ADENOSINE TRIPHOSPHATE, HYPOXANTHINE, AND THE 260/250 ABSORBANCE RATIO IN ADDUCTOR MUSCLES FROM SCALLOP *AEQUIPECTEN TEHUELCHUS* (D'ORBIGNY, 1846)

ABSTRACT The influence of food availability and the reproductive cycle on the postmortem levels of glycogen, adenosine triphosphate (ATP), hypoxanthine, and the 260/250 absorbance ratio in extracts of adductor muscles from scallop (*Aequipecten tehuelchus*) was investigated. Phytoplankton production, measured as chlorophyll "a" concentration, was high in early autumn (March to April) and early spring (September to October). Food availability was low in winter and summer. Specimens in good and poor biological condition, according to the determination of chemical composition and energy content, were found in periods of high and low food availability, respectively. Glycogen and ATP levels were higher in muscles from specimens in better biological condition. The rate of decrease of both glycogen and ATP was not dependent on the biological condition. The values of the 260/250 absorbance ratio were higher in extracts of cold-stored adductor muscle from scallops in better biological condition. Irrespective of the biological condition hypoxanthine increased after 24 h in cold-stored muscles. Thereafter, the highest increments were observed in muscles from specimens in the best biological condition.

KEY WORDS: ATP, biological condition, glycogen, gonadal stages, hypoxanthine, *Aequipecten tehuelchus*

INTRODUCTION

A large amount of scallop is consumed as fresh material and is used as material for dried, smoked, or canned products. In addition to that use, the consumption of frozen scallop adductor muscle has been remarkably increasing in the last years. On the other hand, it is widely accepted that nucleotides influence the taste and flavor of fish and mollusks meat (Matsumoto & Yamanaka 1990).

Nucleotide degradation in postmortem fish muscle proceeds as follows: adenosine triphosphate (ATP) → adenosine diphosphate (ADP) → adenosine monophosphate (AMP) → inosine monophosphate (IMP) → inosine (HxR) → hypoxanthine (Hx) (Kassemsarn et al. 1963, Ehira & Uchiyama 1987). In marine invertebrates, a major route for conversion of AMP to HxR via adenosine (Ado) rather than IMP was proposed (Saito et al. 1958, Arai 1960, Hitlz & Dyer 1970). However, several reports are available on the accumulation of IMP in postmortem molluskan muscle (Sakamoto et al. 1973, Nakamura et al. 1976, Suwetja et al. 1989). Contrary to the results of Saito et al. (1958) and Arai (1960), Suwetja et al. (1989) detected a small amount of IMP in the same species of cephalopods and bivalves. The reason for these apparently contradictory reports could be the different biological condition (season, sex, food availability, physiological condition, etc.) of the specimens analyzed. De Vido de Mattio et al. (1992) reported that glycogen and ATP levels were higher in adductor muscles from the bivalve mollusk *Aulacomya ater ater* (Molina) in good biological condition. In this work, it was also reported that the values of the 260/250 absorbance ratio in perchloric acid muscle extracts from *Aulacomya* specimens in good biological condition were significantly higher than the values from specimens in poor biological condition. Because of that, it was suggested that the biological condition of *Aulacomya* influences the ratio among ATP and catabolite compounds of ATP breakdown in stored muscles (De Vido de Mattio et al. 1992). A poor biological condition in the bivalve mollusk *Aulacomya* was found during the consumption of energy reserves for metabolic requirements and the development of the gonads in winter in response to insufficient availability of food (De Vido de Mattio 1980). Therefore, more investigation is necessary to determine the real influence of either the reproductive cycle or the availability of food on postmortem changes in ATP and its catabolites in invertebrate adductor muscles.

The scallop *Aequipecten tehuelchus* is a rhythmic hermaphrodite with both gonadal growth and gonadal resting periods (Christiansen & Olivier 1971, Lasta & Calvo 1978). Unlike *Aulacomya*, the gonadal growth period of *Aequipecten* occurs with food availability in the environment. The purpose of the present work was to study the influence of both the gonadal cycle and availability of food on postmortem changes in ATP and catabolites compounds of ATP breakdown in adductor muscles of the scallop *Aequipecten tehuelchus* stored at 2–4°C.

MATERIALS AND METHODS

Specimens of *Aequipecten tehuelchus* (D'Orbigny, 1846) were collected in the San Jose Gulf, Chubut, Argentina. Mature specimens, 70 mm in length, were selected. Resting and gonadal growth periods were determined by macroscopic observation and histology of gonads (Lasta & Calvo 1978). After cleaning the shells, adductor muscles were dissected and carefully freed from adhering pancreatic and liver tissues. Adductor muscles were stored at 2–4°C for up to 10 days. Two experimental runs with mollusks in different biological conditions were performed. At zero time and at different periods of storage, adductor muscles from about 30 speci-

mens were cut into small pieces and thoroughly mixed to ensure homogeneity. Aliquots were taken for the following studies.

Proximal Chemical Composition

Lipids were determined from fresh homogenized material using Soxhlet (Pearson 1971). Water content was measured by drying the tissues at 100°C until a constant weight was reached. Glycogen content was determined colorimetrically using the anthrone reagent, according to the method described by Fraga (1956). Protein content was measured by the Lowry method (Lowry et al. 1951). Ash content was measured by ashing the tissue in a muffle furnace at 500°C. In all cases, the results correspond to the mean of triplicate determinations. They are expressed as percentages of the wet weight.

The energy values of the muscles were determined by the percent chemical composition, with Rubner's coefficients (e.g., lipids 9.45, glucides 4.20, and proteins 5.65) (Winberg 1971).

ATP Content

A portion of pooled, cut, and mixed muscles was homogenized with 10% trichloroacetic acid (TCA). The homogenate was centrifuged at 700 × *g*. The residue was extracted again with 5% TCA. The supernatants were combined and neutralized with a 20% KOH solution under cooling with ice. The neutralized extract was centrifuged and the precipitate was washed with 5% TCA neutralized with KOH. Aliquots of supernatants were taken to measure ATP by the luciferin-luciferase assay as described by Romano and Laborde (1978), adapted for bivalve adductor muscles. A PICO-ATP luminometer (Jovin and Ivon, Ste. France) was employed for light peak measurement.

Hypoxanthine

Ten grams of muscles were homogenized in a Waring blender with 30 mL cold 7% perchloric acid for 1 min, then filtered through Whatman 1 filter paper. The extracts were neutralized with 30% KOH. The $KClO_4$ precipitate was removed by centrifugation and the volume of neutralized extracts was adjusted to 50 mL. Hypoxanthine concentration was estimated by xanthine oxidase activity according to the procedure reported by Jones et al. (1964).

The 260/250 Absorbance Ratio

The 260/250 absorbance ratios were determined as the ratio of the absorbance of perchloric acid muscle extracts at 260 nm to that at 250 nm (Korhonen et al. 1990). One gram of tissue was homogenized in a Waring Blender with 25 mL cold 20% perchloric acid for 1 min, then filtered through Whatman 1 filter paper. The filtrate was diluted with three volumes of distilled water. Absorbance was measured immediately using a Beckman DU8 spectrophotometer at wavelengths of 250 and 260 nm.

Statistical Analysis

eans were compared by analysis of variance and the Student's *t*-test. Differences between slopes were determined by the Student's *t*-test.

RESULTS AND DISCUSSION

Because bivalve mollusks are primary consumers, the phytoplankton supplied with particulate organic material constitutes the main source of food. The changes during the year in the phytoplanktonic production, expressed as chlorophyll "a" concentration, are shown in Figure 1. High phytoplankton production can be observed in early autumn (1.8 mg · m^{-3}) and early spring (2.8 mg · m^{-3}). Food availability was low in winter and summer. Lasta and Calvo (1978) reported that the reproduction of the *Aequipecten tehuelchus* occurs as follows: by the end of winter and during early spring, most of the individuals show the first stages of gonad ripening. At the beginning of summer (i.e., during December), the ovocytes increase rapidly in size and ripe animals begin to spawn naturally. The spawning season lasts for most of the summer in the southern hemisphere, from December to February. The gonadal

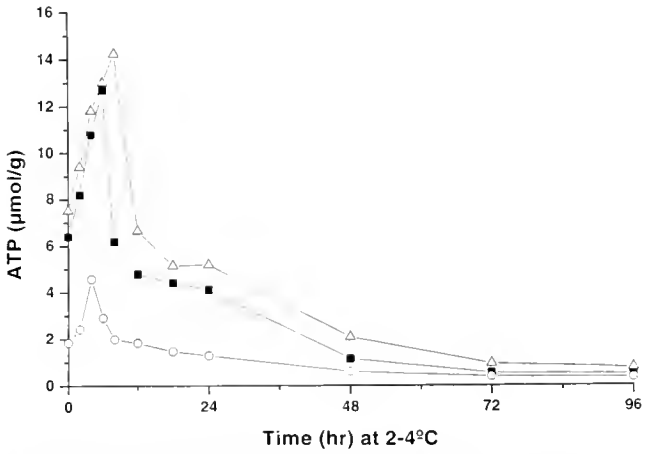

Figure 4. Changes in ATP content in cold-stored muscles. For other details see legend to Figure 3.

resting period starts in early autumn and finishes at the end of winter. Like many other bivalves, scallops have seasonal cycles of energy use that are intimately associated with the reproductive cycle (Ansell 1974, Barber & Blake 1991). The biological condition of scallop at different stages of the reproductive cycle is shown in Table 1. The highest values of the relative percentages of glycogen and proteins were observed in the adductor muscles of specimens at the beginning of the gonadal resting period. Correspondingly, the energy content was higher in these samples and therefore specimens in this period present the best biological condition. The relative percentages of the different components of the adductor muscle and the energy content, except the relative percentage of lipid, were slightly lower in specimens in the gonadal growth period than in those caught at the beginning of the gonadal resting period (Table 1). Because of that, specimens caught during the gonadal growth period remain in good biological condition. Variations in body components indicate either accumulation or use of storage substrates (Barber & Blake 1991, Martinez & Mettifogo 1998). In *Chlamys septemradiata* and *Pecten maximus* energetic reserves of the adductor muscles are used for gonadal maturation, producing an important decrease in the weight of the muscles (Ansell 1974, Comely 1974). Conversely, in *Aequipecten tehuelchus* the weight of the muscles either did not decline or declined slightly during the gonadal growth period (Lasta & Calvo 1978). The results shown in Table 1 and those of Lasta and Calvo (1978) suggest that little of the energetic reserves of the adductor muscles were used for metabolic and reproductive purposes during the period of highest gonadal activity. It could be suggested that the energy requirements for reproduction of *A. tehuelchus* are mainly satisfied by the food taken from the environment. In agreement with these results, it was reported that during artificial conditioning of the sea scallop, *Placopecten magellanicus*, the mean weight of the adductor muscle was more than twice the weight observed in the wild specimen during gametogenesis. This indicates that the scallops were accumulating reserves despite the stress of gamete production (Paon & Kenchington 1995).

Glycogen constitutes about 93% of the total glucides that are present in adductor muscles (De Vido de Mattio 1980). The major anaerobic energy source in postmortem muscle is the breakdown of glycogen. As it can be seen in Figure 2, high and low levels of both glycogen and ATP were found in adductor muscles in periods of high and low food availability, respectively. These results are additional evidence of those energetic reserves that were stored in adductor muscles in periods with high food availability in the environment. Glycolysis profiles of cold-stored adductor muscles

from *A. tehuelchus* in different biological conditions are shown in Figure 3. Irrespective of the biological conditions of the specimens, glycogen content decreased within the first 12 h of storage. Glycogen content decreased slowly thereafter up to the end of storage. No significant differences ($P < 0.05$) in the slope of the curves were found within the first 12 h of storage. The results shown in Figure 3 indicate that the glycolysis rate is not dependent on the initial glycogen content of adductor muscles. Similar results were observed with *Aulacomya* adductor muscles stored at 2–4 C (De Vido de Mattio et al. 1992).

Changes in the ATP concentration in stored muscles are shown in Figure 4. The ATP content increased for a short time after death because the nucleotide is regenerated by degradation of arginine phosphate prior to destruction of ATP. As expected, the maximum ATP content in muscles was dependent on the biological condition of the specimens. After the maximum was reached, the ATP content fell sharply up to 12 h. No significant differences were found in the slopes of ATP decrease. Thereafter, nucleotide levels decreased slightly up to 72 h of storage. The ATP content was unchanged after 72 h.

Based on the measurement of the postmortem conversion of adenosine nucleotides to derivates IMP, HxR, and Hx, the R value was defined as the 250/260 absorbance ratio. Adenosine nucleotides show maximum absorption at 259–260 nm, and IMP, HxR, and Hx at 249–250 nm. The inverse of the R value, the 260/250 absorbance ratio, was successfully used to determine the effects of antemortem stress on the rate of onset of rigor mortis and associated biochemical changes in fish muscle (Korhonen et al. 1990). In addition, it was also successfully used to demonstrate the influence of the biological condition of the bivalve mollusk *Aulacomya* on the ratio among ATP and catabolite compounds of ATP breakdown in cold-stored muscles (De Vido de Mattio et al. 1992). The 260/250 absorbance ratios of perchloric acid extracts of stored molluskan adductor muscles are shown in Table 2. The values of the 260/250 absorbance ratio of about 1.26 and 1.22 were obtained at zero time of storage for samples from specimens in gonadal resting period with good and poor biological condition, respectively. These values were significantly different ($P < 0.01$). Khan and Frey (1971) reported initial values of about 1.2 for well-rested beef and pork, the values subsequently declining to 0.89 or lower upon the passing of the samples into rigor. Korhonen et al. (1990) reported initial values of about 1.07 and 0.97 for muscles from unstressed and stressed fish, respectively. The initial values found by us in adductor muscles from scallop were similar to those of beef and pork and slightly lower than those reported for adductor muscles of *Aulacomya*. During the storage, the values of the 260–250 absorbance ratio of muscle extracts from specimens in poor biological condition were significantly lower than the values of muscle extracts from specimens in good biological condition ($P < 0.01$ at 24, 48, and 72 h; $P < 0.05$ at 96 and 120 h) (Table 2). In the experiments shown in Table 2 only specimens in gonadal resting periods were used. Therefore, an influence of the food intake on postmortem changes in the ratio among ATP and catabolite compounds of ATP breakdown in stored muscles might be suggested. The profiles of Hx production in cold-stored adductor muscles of scallop are shown in Figure 5. Irrespective of either gonadal stage or biological condition of specimens, Hx levels linearly increased about 230% during the first 24 h. Thereafter, the increment in the Hx content was higher in muscles of scallop in better biological condition. In agreement with these results it was reported that the Hx levels reached since day 5 in cold-stored adductor muscles from *Aulacomya* in good biological condition were higher than the levels from specimens in poor biological condition (De Vido de Mattio et al. 1992).

The results of this paper demonstrate that glycogen and ATP levels were higher in specimens in good biological conditions. The rate of decrease of both glycogen and ATP in adductor muscles was not dependent on the biological conditions of the scallops. Food availability influences both the biological condition of scallops and the postmortem changes in the ratio among ATP and catabolite compounds of ATP breakdown in stored muscles.

KING SCALLOP (*PECTEN MAXIMUS*) DEPURATION TRIALS

PHILIP HEATH[1]* AND MARTIN PYKE[2]

[1]*Centre for Marine Resources and Mariculture (C-Mar), The Queen's University of Belfast Marine Laboratory, The Strand, Portaferry, County Down, BT22 1PF, Northern Ireland, United Kingdom;*
[2]*Seafish Industry Authority (SEAFISH), Seafish Technology, Seafish House, St Andrew's Dock, Hull, HU3 4QE, United Kingdom*

ABSTRACT Preliminary trials were undertaken to assess the potential for depuration (purification) of diver harvested king scallops (*Pecten maximus*) under a range of temperatures and shellfish to water ratios. Scallops taken from class B waters were held for 42 hours in standard design depuration systems. Bacteriological analysis indicated a significant decrease in *E. coli*. and total viable count (TVC) at all temperatures and water ratios after the 42 hour depuration period. Mortalities at temperatures above 20.5°C and increased ammonia levels at low shellfish to water ratios indicated that acceptable depuration conditions lie between 6.6°C and 15.6°C at shellfish to water ratios in excess of 1:12. Scallops held upside down also depurated effectively, although TVC indicated that in this orientation depuration was less effective than in scallops held the right way up.

KEY WORDS: bacteriological analysis, depuration, *Pecten maximus*

INTRODUCTION

In order to reduce the risks associated with eating raw or lightly cooked bivalve mollusks the food safety (hygiene) regulations 1998 (Fishery Products and Live Shellfish) require that bivalve mollusks from class B waters be depurated (purified) to reduce bacteriological contamination before releasing for human consumption. The Seafish Industry Authority (SEAFISH) has established protocols for depuration, based on temperature, salinity, flow rates, oxygen levels and loading density, for a number of shellfish species. These include; cockles (*Cerastoderma edule*), mussels (*Mytilus edulis*), oysters (*Ostrea edulis* and *Crassostrea gigas*) and razor clams (*Ensis* sp.) (Boulter et al. 1994, SEAFISH 1997). While protocols for de-gritting king scallops (*Pecten maximus*) have been set (McNamara 1996) there are currently no protocols for depuration of king scallops.

Currently there are three scallop farms in Northern Ireland that either have full culture licenses or are in the process of receiving a culture license. One of these farms is known to be in a "Class B, shellfish harvesting area" and at least one other farm is likely to be classified as "B" when production starts. It is therefore imperative that depuration criteria be set for scallops in Northern Ireland in the near future.

An initial trial aimed at depurating king scallops was run in August 2000, using SEAFISH standard design experimental depuration tanks.

Aims

- To determine whether depuration of king scallops is possible using theoretically normal conditions (salinity 31 psu and temperature 10°C–15°C)
- To establish the temperature range over which king scallops will depurate under normal saline conditions (31 psu)
- To establish the effect of shell orientation on king scallop depuration
- To determine a suitable shellfish to water ratio for depuration
- To determine the effect of depuration conditions on post depuration survival

MATERIALS AND METHODS

On October 17, 2000 approximately 100 kg of diver harvested king scallops were collected from Mulroy Bay, Co. Donegal and transported by road to the Centre for Marine Resources and Mariculture (C-Mar), Portaferry, Northern Ireland, a journey lasting 3.5 hours.

On October 18, the scallops were transferred to plastic trays (NW trays) (dimensions 480 mm × 480 mm × 60 mm with 4 mm square holes), in a cupped side down position, at a density of 10 scallops per layer. These trays are used for scallop cultivation in the UK and Ireland (Hardy, 1991). Eight stacks of trays, seven layers deep were then transported 25 miles to Bangor, County Down by road. They were then transported by boat and placed on the sea bed at a shellfish cultivation site off Greencastle, inner Belfast Lough. (50°40.50′ N, 005°52.77′ W) This site is known to produce "Class B" mussels.

On November 28, four tray stacks of scallops were recovered from Belfast Lough. On December 11, the remaining four tray stacks were recovered. The surviving scallops were removed from the trays immediately and placed cupped valve down in fish boxes and covered with damp sacking. A sample of the surviving scallops was packed in a cool box and sent by courier to Aqualab, Killybegs, County Donegal, for microbiological analysis. The remaining scallops were returned to the C-Mar Laboratory. Emersion time for scallops used for depuration trials did not exceed 3.5 hours.

On arrival at Portaferry the scallops were weighed and placed into NW trays at a maximum of 10 scallops per tray, approximately 30 live scallops (5kg) for each trial (Table 1).

The trays were then transferred to experimental scale depuration tanks (Seafish Industry Authority standard design) for 42 hours. Temperature, salinity, ammonia ($NH3 + NH_4^+$) and oxygen levels were monitored throughout the trials. Salinity measurements were recorded with a WTW LF325 conductivity meter, ammonia measurements were made with a Bran Leubbe (Germany) autoanalyser (Salicylate method) and oxygen and temperature measurements were taken with a WTW Oxi 340 oxygen meter.

On completion of the depuration trial the tanks were drained and the scallops removed. All scallops were weighed and assessed for survival.

Samples of 10 scallops, randomly selected from each trial, were

packed in a cool box and sent by courier for post depuration microbiological analysis at Aqualab. Samples were screened in triplicate for *E. coli* (MPN $100g^{-1}$ flesh), and Total Viable Count (ACC cfu g^{-1})(30°C 48 h). Pre-depuration samples were also screened for Salmonella.

The remaining scallops were returned to NW trays in a flow through system with ambient seawater (8.5°C and 31 psu) and held for a further seven days to assess survival post depuration.

The trial aimed to assess three variables within the depuration system:

1. Temperature
   temperatures of 5, 6, 10, 14, 16, 20 and 24°C were tested at 31 psu and a shellfish to water ratio of 1:15;
2. Shellfish to Water ratio
   calculated as 1kg of animals in 1l of water being equivalent to a ratio of 1:1. Ratio's tested were 1:3, 1:6, 1:9, 1:12 and 1:15. Temperatures were held between 13°C and 14°C;
3. Shell orientation
   scallops were held either cupped valve down (right way up) or cupped valve up (upside down) at 31 psu and 14°C and shellfish to water ratio of 1:12;

Flow rates within the systems were held at a constant 750 l hr^{-1}.

RESULTS

Pre Depuration

Pre depuration samples (Table 1) indicated that on both sample dates scallops collected from Belfast Lough had *E. coli* counts that would classify them as "Class B". However, scallops collected on November 28 had significantly lower *E. coli* levels and TVC (1910 MPN $100g^{-1}$ and 4.0×10^3 cfu g^{-1} respectively) than those collected December 11, (2733 MPN $100g^{-1}$ and 499.4×10^3 cfu g^{-1} respectively). No salmonella was found.

Temperature

The investigation showed depuration at temperatures between 6.6°C and 24.5°C reduced *E. coli* levels in scallops from 1910–2733 *E. coli* $100g^{-1}$ of flesh (Class B) to a level of around 30 *E. coli* $100g^{-1}$ (Class A) in 42 hours (Table 1). Depuration at 4.5°C reduced *E. coli* levels to 437 *E. coli* $100g^{-1}$, significantly less than at higher temperatures and not sufficiently for the animals to reach the *E. coli* level required for A classification.

TABLE 1.

Pre and post depuration TVC ($\times 10^3$ g^{-1}) and *E. coli* (100 g^{-1}) counts for scallops (*Pecten maximus*) depurated at temperatures between 5°C and 20°C upside down and in shellfish to water ratios between 1:3 and 1:15 (14°C).

Trial	Pre dep. TVC ($\times 10^3$ g^{-1})	Pre dep. E. coli (100 g^{-1})	Post dep. TVC ($\times 10^3$ g^{-1})	Post dep. E. coli (100 g^{-1})
Temp. 5	494.3	2733	2.8 ± 1.3	437
Temp. 6	4.0	1910	0.6 ± 0.1	32
Temp. 10	4.0	1910	0.8 ± 0.5	<30
Temp. 14	4.0	1910	1.0 ± 0.4	<30
Temp. 15	4.0	1910	1.1 ± 0.6	<30
Temp. 20	4.0	1910	2.3 ± 0.7	32
Temp. 24	494.3	2733	3.9 ± 3.8	<30
Upside down	494.3	2733	1.5 ± 0.4	<30
Ratio 1:3	494.3	2733	1.5 ± 0.4	<30
Ratio 1:6	494.3	2733	2.6 ± 0.5	<30
Ratio 1:9	494.3	2733	2.7 ± 1.5	<30
Ratio 1:12	494.3	2733	0.7 ± 0.2	34
Ratio 1:15	4.0	1910	1.0 ± 0.4	<30

Depuration reduced TVC at all temperatures (Fig. 1). A significant correlation ($p < 0.05$) was found between temperature and post depuration TVC for scallops depurated between 6.6 and 20.5°C.

Scallop survival was high at all temperatures (Table 2) but two mortalities and one gaping animal were observed in scallops held at 24.5°C. No mortalities were observed among the surviving scallops seven days post depuration.

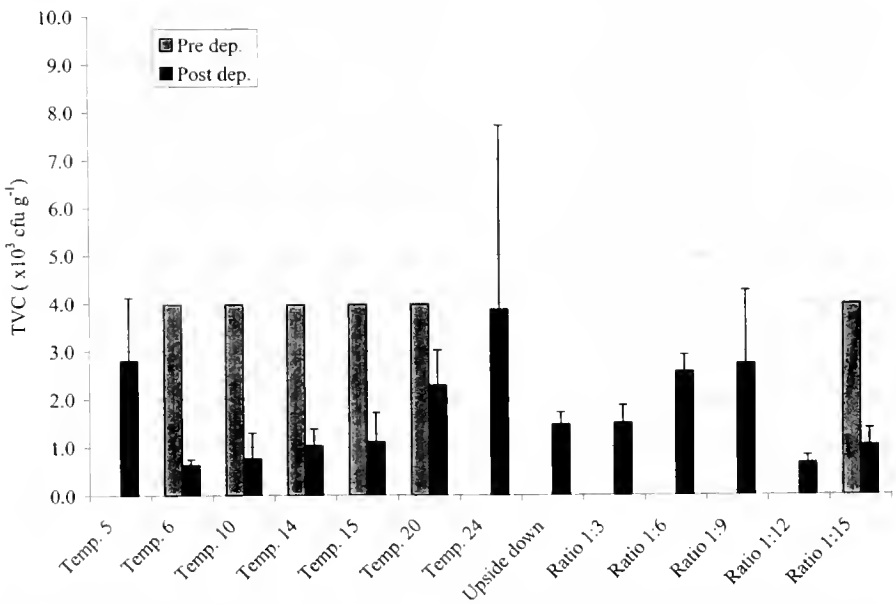

Figure 1. Pre and post depuration Total Viable Count (TVC) for scallops (*Pecten maximus*) depurated at temperatures between 5°C and 24°C, upside down and in shellfish to water ratios between 1:3 and 1:15.

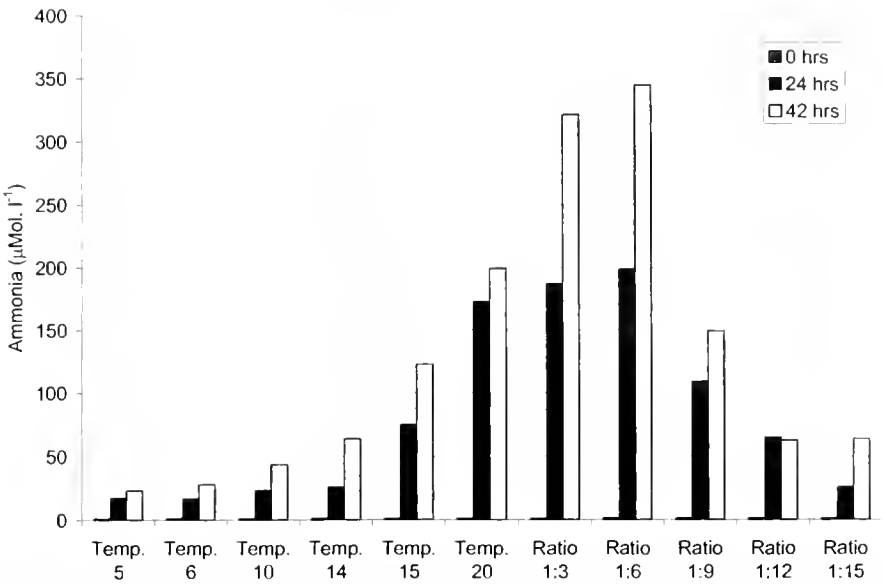

Figure 2. Pre depuration, 24 hours and 42 hours ammonia values for scallops (*Pecten maximus*) depurated at temperatures between 5°C and 20°C, upside down and in shellfish to water ratios between 1:3 and 1:15.

Oxygen levels remained in excess of 91% saturation in all tanks during the trial. Ammonia values for the trial at 24°C were contaminated and were therefore rejected. Values for temperatures between 4.5°C and 20°C increased in all tanks during the trial, showing a significant linear correlation ($r = 0.928$) between temperature and ammonia levels.

Orientation

Depuration of scallops held upside down at an average temperature of 14.2°C showed a reduction in *E.coli* from 2733 *E coli* $100g^{-1}$ (Class B) to a level of <30 *E coli* $100g^{-1}$ (Class A) in 42 hours.

Depuration also reduced TVC, but levels remained significantly higher than for scallops held at the same temperature and shellfish to water ratio the right way up ($p < 0.05$).

Oxygen levels remained in excess of 93% throughout the trial and no mortalities were observed during the depuration period or seven days post depuration.

Shellfish to Water Ratio

Depuration of scallops in shellfish to water ratios of between 1:3 and 1:15 reduced *E. coli* levels from 2733 *E coli* per 100g of flesh (Class B) to a level of around 30 *E coli* per 100g of flesh (Class A) in 42 hours.

TVC's were reduced by depuration for all shellfish to water ratios. Further analysis of the data (ANOVA and Tukey's b post hoc test) (Sokal and Rolf 1995) indicate that, for trials which started with the same pre depuration TVC, the shellfish to water ratio of 1:12 resulted in a significantly lower TVC than for the lower shellfish to water ratios ($p < 0.04$) (Fig. 1).

A single mortality was observed in each of the 1:3 and 1:6 water ratio trials during depuration. No mortalities were observed among the surviving scallops seven days post depuration.

Oxygen levels remained in excess of 91% saturation in all tanks during the trial. Ammonia values increased in all tanks during the experiment (Fig. 2) with final values in shellfish to water ratios of 1:3 (321 μmol l^{-1}) and 1:6 (344 μmol l^{-1}) approximately double those for the 1:9 ratio (149 μmol l^{-1}) and five times those for ratios of 1:12 (63 μmol l^{-1}) and 1:15 (62 μmol l^{-1}).

DISCUSSION

The study shows that it is possible to hold and depurate king scallops over a 42-hour period. However, in order to provide meaningful information to industry and to ensure that in scallops depurated for human consumption, bacterial loads are always reduced to acceptable levels, it is necessary to define more precisely that range of conditions under which scallops depurate most effectively.

TABLE 2.

Depuration temperature, number and biomass of scallops used and percentage survival, during depuration and seven days post depuration (+7) for scallops (*Pecten maximus*) depurated at temperatures between 5°C and 20°C, upside down and in shellfish to water ratios between 1:3 and 1:15 (14 C).

Trial	Temperature (°C)	No. scallops	Mass (kg)	Survival (%)	Survival +7 (%)
Temp. 5	4.6 ± 0.6	15	2.94	100	100
Temp. 6	6.6 ± 1.3	30	6.12	100	100
Temp. 10	9.9 ± 1.3	30	5.13	100	100
Temp. 14	14.1 ± 1.6	30	5.54	100	100
Temp. 15	15.6 ± 0.6	30	5.54	100	100
Temp. 20	20.5 ± 0.5	30	5.7	100	100
Temp. 24	24.5 ± 0.7	15	2.14	80	100

Ratio 1:3	12.9 ± 1.0	30	5.54	93	100
Ratio 1:6	13.3 ± 0.7	30	5.83	93	100
Ratio 1:9	14.2 ± 0.8	30	5.71	100	100
Ratio 1:12	13.4 ± 0.6	30	5.72	100	100
Ratio 1:15	14.1 ± 1.6	30	5.54	100	100

TABLE 3.

Maximum and minimum temperatures recommended for shellfish depuration (after SEAFISH 1997)

Species	Minimum temperature	Maximum temperature
Mussels (*Mytilus edulis*)	5°C	15°C
Native oysters (*Ostrea edulis*)	5°C	15°C
Pacific oysters (*Crassostrea gigas*)	8°C	18°C
Cockles (*Cerastoderma edule*)	7°C	16°C

The data indicate that the temperature range for scallop depuration, which ensures an acceptable reduction in bacterial levels (*E. coli.*) and does not lead to mortalities during the depuration process, is between 6.6 ± 1.6°C and 20.5 ± 0.5°C. This is greater than the range (10–18°C) recommended by McNamara (1996) for degritting scallops. Temperature ranges for depuration of other bivalves vary with species (Table 3), but can be as low as 5°C for species native to UK waters (SEAFISH 1997).

Duncan (1993) indicated that mortalities related to exposure to ammonia occurred in king scallops at levels around 518 μmol l^{-1} but post exposure mortalities were observed for constant exposure to ammonia concentrations as low as 64 μmol l^{-1} (96 hours). As exposure is not at a constant level in a depuration system, but builds up over the depuration cycle higher final concentrations may be acceptable. To ensure that scallops are not exposed, at any point during the cycle, to ammonia concentrations in excess of 64 μmol l^{-1} then a shellfish to water ratio in excess of 1:12 is recommended at a maximum temperature of 15.6 ± 0.6°C. High ammonia levels may have been the cause of the mortalities observed in shellfish to water ratios of 1:3 and 1:6.

Survival of all scallops held for seven days post depuration indicates that the depuration process does not cause stress to the animals which leads to post depuration mortality. This is important for the scallop processing industry where supply of live product to market can attract a premium.

Further work is required to assess the effects of salinity, oxygen levels and pre depuration handling on depuration performance in the king scallop.

THE EFFICIENCY AND SELECTIVITY OF SPRING-TOOTHED SCALLOP DREDGES: A COMPARISON OF DIRECT AND INDIRECT METHODS OF ASSESSMENT

BRYCE D. BEUKERS-STEWART,* STUART R. JENKINS, AND ANDY R. BRAND
University of Liverpool, Port Erin Marine Laboratory, Port Erin, Isle of Man, IM9 6JA, United Kingdom

ABSTRACT The efficiency and selectivity of spring-toothed scallop dredges was assessed using a concurrent depletion experiment and diver survey of dredge tracks on a north Irish Sea fishing ground. Two size classes of the scallop, *Pecten maximus* (L. 1758), were examined: below minimum legal landing size (MLLS), (90–109 mm shell length (SL)) and above MLLS (>109 mm SL). Estimates of efficiency from the depletion experiment (24.3% and 29.5% respectively) were consistently lower than those from the diver surveys (38.0% and 40.7% respectively). This difference appeared to be due to inherent variation in the efficiency of scallop dredges rather than bias from either technique. This emphasizes the need for error terms to be built into estimates of dredge efficiency. The diver survey also found that dredges were highly selective toward scallops greater than 90 mm SL, catching only 3.0% or less of individuals below this size. Consequently, the diver survey provided a much more accurate assessment of scallop size and age composition than dredge surveys. Dredge efficiency was also assessed for four species of benthic fauna commonly taken as by-catch in the local fishery. Estimates of efficiency from the depletion experiment were found to include a considerable amount of indirect fishing mortality. When efficiency was defined as total mortality due to fishing (the combination of catch and indirect fishing mortality), estimates from the depletion experiment and diver surveys were in close agreement. For two species, *Luidia ciliaris* (Phillipi 1837) and *Cancer pagurus* (L. 1758), these efficiency or total mortality estimates were approximately 45% and 68% respectively, emphasizing the impact scallop dredging might have on non-target species. In summary, we recommend that if possible, depletion experiments should be combined with diver surveys when assessing scallop dredge performance. Diver surveys provided additional information on dredge selectivity along with an improved measure of the variance in dredge efficiency estimates.

KEY WORDS: scallops, dredge efficiency, gear selectivity, *Pecten maximus*, depletion experiment, diver survey, stock assessment

INTRODUCTION

Accurate assessment of the state of fish and shellfish populations requires conversion of the results from stock surveys into estimates of "true" abundance (Dare & Palmer 1994). Scallop (Pectinidae) populations are often surveyed by towing commercial scallop dredges along the seabed. This technique enables relatively rapid coverage of large areas, increasing the relevance of results to commercial fisheries. In general, however, scallop dredges are relatively inefficient (estimates range from 2.1% (Caddy 1968) to 56% (Currie & Parry 1999)) and tend to be selective toward large individuals (Chapman et al. 1977, Dare et al. 1993, Fifas & Berthou 1999). The selective nature of dredges provides little information to fisheries managers on the abundance of upcoming year classes of young/small scallops.

Many factors are known to affect the efficiency and selectivity of scallop dredges. These include mechanical aspects such as dredge set up and design (e.g. teeth length, angle and spacing, belly ring diameter and teeth bar tension), operational factors such as towing speed, duration and warp length, and environmental conditions such as sea state and the substrate type of the seabed (for review see Dare et al. 1993). In addition, efficiency and selectivity may vary between scallop species according to their swimming behavior and ability to recess into the sediment (Caddy 1968, Chapman et al. 1977, Dare et al. 1993). Hence any estimate of dredge efficiency will only be relevant to the conditions under which it was measured or must be seen as an estimate of the average situation (Somerton et al. 1999).

The efficiency and selectivity of scallop dredges may be measured by either indirect or direct methods. One indirect method is to measure scallop density and population structure at a study site using a highly efficient technique such as diver surveys and then compare this to a survey of the same area using scallop dredges (e.g. Fifas 1991). Another, more commonly used indirect method is through depletion (DeLury 1947, Joll & Penn 1990, Hilborn & Walters 1992, Currie & Parry 1999). Depletion experiments are based on fitting a model to the relationship between catch rate and cumulative catch when a given area of seabed is fished repeatedly. The main advantage of depletion experiments is that they are possible on a large scale, are not limited to shallow water and are therefore particularly relevant to stock surveys and commercial fisheries. However, large numbers of replicate tows may be needed to sufficiently deplete populations and take account of variations in gear efficiency and patchiness of the stock. Regression equations used to calculate efficiency in depletion experiments can therefore be highly susceptible to outliers. Depletion experiments also provide only limited information on selectivity, as size-classes that are rarely caught will not be depleted sufficiently for efficiency to be calculated.

Direct methods for calculating scallop dredge efficiency and selectivity include monitoring the catch rate of tagged scallops seeded on the seabed at a known density (e.g. Dare et al. 1993). Possibly the most direct technique, though, is to survey dredge tracks on the seabed and compare what has been left behind with what has been caught (e.g. Caddy 1968, Chapman et al. 1977, Mason et al. 1979). Ideally, such surveys are done by divers who can count the scallops left in the dredge tracks and collect them for later measurement and ageing. Diver surveys are generally thought to be close to 100% efficient for surveying scallop populations (Mason et al. 1979, Coleman 1998), although very small individuals may be missed, which could lead to overestimates of dredge efficiency for this size class. The spatial patchiness of scallop populations (Brand 1991) may also necessitate that divers cover large areas in order to reduce variability in efficiency estimates. This generally restricts diver surveys of dredge tracks to relatively

*Corresponding author. Tel.: +44-1624-831038; Fax: +44-1624-831001; E-mail:brycebs@liverpool.ac.uk

shallow fishing grounds and demands a high number of diver hours.

All of these methods for estimating scallop dredge efficiency and selectivity have certain advantages and disadvantages. To date, however, there have been no direct comparisons of the effectiveness of these different methods when applied to the same local scallop population at the same time. In this study we aimed to compare the outcomes and effectiveness of a concurrent depletion experiment and diver survey of dredge tracks on the same fishing ground. The work was done in the north Irish Sea off the Isle of Man, which has supported a commercial fishery for the great scallop, *Pecten maximus*, for over 60 years. Over 20 years of data from detailed stock surveys of *P. maximus* around the Isle of Man are available and interpretation of these data would be greatly enhanced by accurate estimates of dredge efficiency and selectivity. In addition to examining results for *P. maximus*, we also compared efficiency estimates and non-target mortality for four species of benthic megafauna that are commonly taken as by-catch in the Isle of Man scallop fishery. Accurate efficiency estimates for these species would allow further predictions to be made regarding the environmental impact of scallop dredging around the Isle of Man, a subject that has received considerable recent attention (e.g. Hill et al. 1999, Bradshaw et al. 2000, Kaiser et al. 2000, Veale et al. 2000b).

MATERIALS AND METHODS

Dredging for both the depletion experiment and diver surveys was done by the RV Roagan, a 24-m converted beam trawler, on the Bradda Inshore fishing ground off the Isle of Man on five days between July 12 and July 21, 2000. On each day of the study two tows were done for the dive surveys (one in the morning and one in late afternoon), with three tows in between for the depletion experiment. Weather conditions were very calm on survey days, with wind speeds less than 10 knots. Sea temperature was approximately 15°C and underwater visibility 3 to 5 m. Water depth in the study area ranged from 29m to 35m and sediment was generally a gravelly mixture of sand, shell, and mud with occasional large stones (Jenkins et al. 2001). These features are typical of many of the scallop fishing grounds around the Isle of Man. A gang of four Newhaven spring-toothed scallop dredges (total width 3.50 m) was towed off each side of the boat. Mean tooth length on the dredges at the start of the study was 76 mm (± 1 mm SE). To simulate our stock surveys and local commercial practice, all tows were approximately two nautical miles (3,704 m) in length, which at an average speed of 2.77 knots (5.13 km/hour) lasted 45 to 50 minutes. At the end of each tow the catch was landed and sorted on the deck. All scallops (*Pecten maximus*) were counted, measured, and aged to the nearest year using clearly visible validated annual shell rings (Allison et al. 1994). Numbers of the four other most common species of benthic fauna in the catch, the starfish *Asterias rubens* (L. 1758), *Luidia ciliaris*, *Porania pulvillus* (Müller 1776), and the edible crab, *Cancer pagurus*, were also counted.

Depletion Experiment

An area of seabed, two nautical miles (3,704 m) long by 40 m wide (54°07′N, 4°48′W), was selected and identified for the depletion experiment using an onboard differential global positioning system (DGPS) linked with Microplot software (Sea Information Systems, Aberdeen). Fourteen tows were done haphazardly within this area, after which time the seabed had been dredged an average of 2.45 times. Efficiency of the dredges was calculated for two size classes of scallops, 90 to 109mm shell length (SL), (under the minimum legal landing size (MLLS)) and 110mm SL or greater (above the MLLS), using the Leslie-Delury method (DeLury 1947, Hilborn & Walters 1992). This method plots the number of scallops caught during each sequential tow against the cumulative catch. The slope of the regression fitted to this plot gives a measure of the rate at which catch rates have changed during the experiment. When this slope is multiplied by the ratio of the total area of the experimental plot to the area covered by each tow, a measure of efficiency is given. In this experiment the ratio was 148,160 m^2 (the area of the plot) divided by 25,928 m^2 (the width of 8 dredges (7 m) × the length of the tow (3,704 m)), which equals 5.71428. Standard errors of these efficiency estimates were calculated from the standard error of the slope of each regression. Regression slopes for the two size classes of scallops (90 to 109 mm and >110 mm) were compared by ANCOVA with the fixed factor being size class, the dependent variable number of scallops caught per tow and the covariate cumulative catch. Differences in efficiency are indicated by a significant interaction between cumulative catch and size class.

Using the same method the overall efficiency of the dredges for catching the four by-catch species, *A. rubens*, *L. ciliaris*, *P. pulvillus*, and *C. pagurus*, was also calculated.

Diver Surveys

Diver surveys of dredge tracks were done on 10 tows of scallop dredges, conducted within an area of 2.74 km^2, approximately 200 m inshore from the depletion experiment plot. This spatial separation was necessary to ensure the safety of the divers, as the diver survey was conducted at the same time as the depletion experiment. Dredge tows were done using the same configuration and procedures described above and were of as similar distance and duration as possible. Sorting and measuring of the catch was also done as above.

During these tows the dive support vessel, RV Sula, dropped buoyed shot lines at two points, approximately 500 m apart, between the two sets of dredge tracks. This was done on both the first and second half of tows during the course of the study. After a period of 15 to 30 minutes, between two and four pairs of divers descended to the dredge tracks. The divers then swam along the tracks as far as possible given depth and air restrictions and counted all benthic fauna encountered. All scallops were also collected to allow measurement and ageing on the surface. The distance covered by the divers was calculated from DGPS readings taken from the buoyed shot lines and surface marker buoys released by the divers at the end of their surveys.

From these dive surveys the efficiency of the scallop dredges for catching scallops and the four by-catch species could be calculated using the following formula:

$$\text{Efficiency} = (\text{Density from dredges} / \text{Density from dredges + dive surveys}) \times 100$$

For the purposes of the study this formula assumes the dive surveys to be 100% efficient, which may or may not always be the case (see discussion). Data from the dive surveys were pooled for each tow (ie. from two to four pairs of divers) to allow tows to be used as replicates. The effect of number of tows (or replicates) on the magnitude and variability of efficiency estimates for catching all scallops was plotted. Along with overall efficiency estimates,

TABLE 1.

Comparison of mean scallop dredge efficiency estimates from the depletion experiment (n = 14) and diver surveys of dredge tracks (n = 10 for *Pecten maximus*).

Species	Depletion experiment				Diver surveys	
	R^2	P	Efficiency	SE	Efficiency	SE
Pecten maximus (all)	—	—	—	—	22.69	4.65
P. maximus (<90 mm)	—	—	—	—	3.01	0.66
P. maximus (90–109 mm)	0.64	0.001	24.34	5.14	37.99	3.73
P. maximus (110 + mm)	0.65	<0.001	29.54	6.29	40.07	5.05
Cancer pagurus	0.50	0.005	68.45	20.00	24.97	—

efficiency was calculated for three size classes of scallops; less than 90 mm SL, 90-109 mm SL and 110mm SL or greater. A 1-way ANOVA, followed by a Tukey's test, was run on these data to determine if there were any differences in efficiency for the different size classes. These efficiency estimates were also compared with those from the depletion experiment.

Size and age compositions of scallops collected during the diver surveys were also compared with those from the dredge catch to further investigate the selectivity of the scallop dredges. By combining data from the dive surveys and dredge catches, estimates of age and size composition, and density, at the study site were also calculated.

RESULTS

Depletion Experiment

The slopes of regressions between sequential catches and cumulative catch for the two size classes of scallops and for *Luidia ciliaris, Porania pulvillus* and *Cancer pagurus* were significant (Table 1). This allowed efficiency estimates to be calculated for these five groups but not for the starfish *Asterias rubens*. Regression slopes, and therefore efficiency estimates (24.3% and 29.5%), were not significantly different for the two size classes of scallops (Table 2). For the by-catch species, efficiency ranged from 21.4% for *P. pulvillus* to 68.5% for *C. pagurus* (Table 1).

Diver Survey

During the diver survey a total of 28 dives (one pair of divers per dive), covering a distance of 2.99 km, were done on the dredge tracks. From these surveys the overall efficiency of the dredges at catching scallops was calculated as 22.7% (± 4.7 SE). The magnitude and variability of efficiency estimates was relatively stable after five tows (Fig. 1). Efficiency was significantly lower for scallops less than 90 mm SL (3.0%) than for larger scallops (38.0% and 40.7%; Tables 1 and 3, Fig. 2).

The interaction between size and cum. catch (cumulative catch) tests for differences in efficiency.

Comparison of the Depletion Experiment and Diver Surveys

For scallops greater than 90 mm SL the diver survey estimates of efficiency were approximately 10 to 15% higher than those from the depletion experiment (38.0% and 40.7% compared to 24.3% and 29.5%; Table 1, Fig. 2). For two of the by-catch species, *L. ciliaris* and *C. pagurus*, efficiency estimates from the diver surveys were less than half those from the depletion experiment (*L. ciliaris*: 20.4% compared to 47.5% and *C. pagurus*: 25.0% compared to 68.4%; Table 1). For the starfish *P. pulvillus*, however, estimates of efficiency from the two methods were similar (Diver surveys: 16.3%, Depletion experiment 21.4%). Unfortunately, due to low numbers of these by-catch species on individual dives, this dive survey data had to be pooled and results from the two methods could not be compared statistically. The diver surveys also gave an efficiency estimate of 9.3% for the starfish *A. rubens* but there was no comparable estimate from the depletion experiment.

Analysis of scallop size and age structures showed considerable differences between the diver surveys and the dredge catches.

Data were Varcsine transformed to meet assumptions of normality and homogeneity of variance.
Results of Tukey's HSD test comparing efficiency estimates from the diver surveys for the three different size classes of scallop, *P. maximus*: (<90 mm) < (90–109 mm) = (110+ mm).

Scallops collected by the dredges were mainly in the 100–109 mm SL size class, while the most common size class collected by divers was 80–89 mm SL (Fig. 3a). In addition, approximately 30% of the scallops collected by divers were less than 80 mm SL, whereas these scallops were almost entirely absent from the dredge catches. This pattern was reflected by data on age composition (Fig. 3b). Most scallops caught by the dredges were 3-year-olds, while most collected by the divers were 2-year-olds. One-year-olds were not particularly common in the diver surveys (7.7%) but they were almost completely absent from the dredge catches. In both cases the combined size and age compositions were much better represented by the diver surveys than by the dredge catches. By combining the dredge catches with the diver surveys, the density of scallops, *P. maximus*, at the study site was estimated to be 4.4 per $100m^2$ (± 0.7 SE).

DISCUSSION

For the scallop, *Pecten maximus*, both the depletion experiment and the diver surveys produced relatively precise estimates of dredge efficiency that were within the range reported in other studies (Chapman et al. 1977, McLoughlin et al. 1991, Dare et al. 1993, Currie & Parry 1999). Estimates from the diver surveys, however, were moderately, but consistently, higher than those from the depletion experiment. This could be due to biases in either method, or a combination of both.

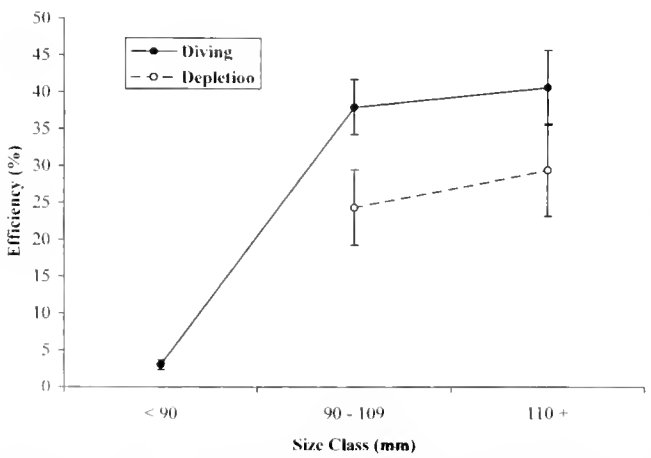

Figure 2. A comparison between dredge efficiency estimates (mean ± SE) from the depletion experiment (n = 14) and diver survey (n = 10) for three size classes of scallop, *Pecten maximus*.

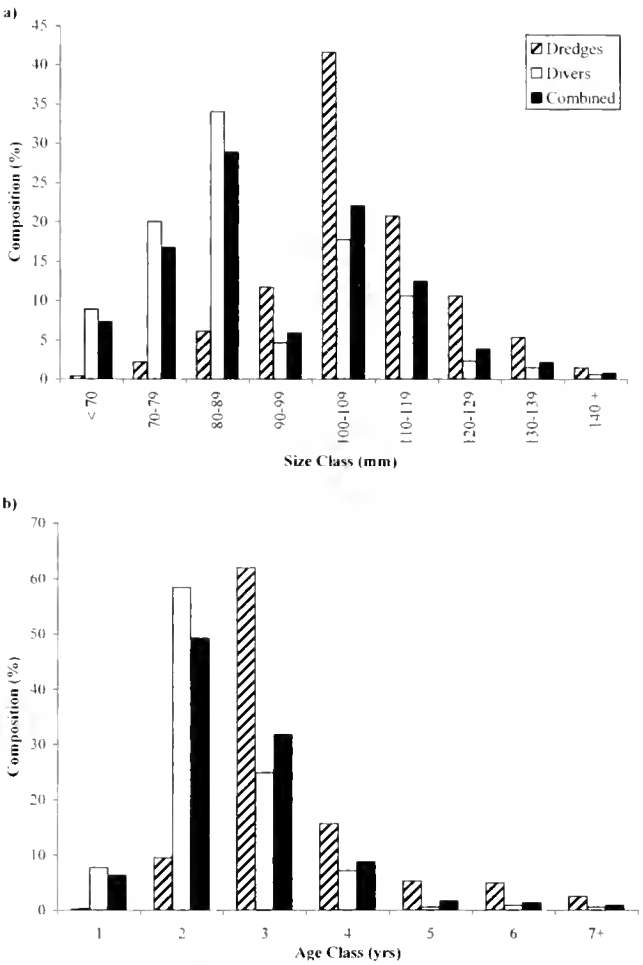

Figure 3. A comparison of the percentage composition of a) size classes and b) age classes of scallops, *Pecten maximus* collected by divers and dredges during the diver survey (n = 350 for divers and n = 2052 for dredges).

Depletion experiments are most effective when examining closed populations with little or no recruitment or natural mortality (Hilborn & Walters 1992). Although such populations rarely exist, conducting a depletion experiment over a short period of time (as in this study) will often negate the effects of recruitment and mortality (Joll & Penn 1990). Movement of the target species into or out of the study area may be more of a problem (Hilborn & Walters 1992). Given the relatively narrow width (40 m) of the depletion experiment plot, it is possible that scallops were moving into the plot during the course of the study. This would have lowered efficiency estimates. A wider plot would have reduced the potential for this to be a problem. In this study, however, we were aiming to replicate our stock surveys, which consist of long parallel tows. Without considerably more effort a wider plot would have necessitated shorter tows with frequent hauling of the gear. This may well have affected dredge efficiency estimates (Dare et al. 1993), making them less relevant to the commercial fishery. In addition, *P. maximus* is one of the most sedentary species of scallop (Brand 1991) and in a tagging study by Howell & Fraser

(1984), 60% of individuals moved less than 30 m after 18 months. Immigration is therefore likely to have had only had a small effect on our results.

Another aspect that may have affected the results from the depletion experiment is a change in the catchability of scallops during the study (Hilborn & Walters 1992). Repeated dredging of an area may cause scallops to become unrecessed, even if they are not caught (Currie & Parry 1999). This would actually have increased the efficiency of the dredges, however, whereas the depletion experiment produced lower efficiency estimates than the diver survey.

One factor that may have biased the diver survey estimates is patchiness of the scallop population (Brand 1991). Despite surveying almost 3 km of dredge tracks, 74 km of tracks were left unsurveyed. If, by chance, dive surveys focused on low-density patches of scallops, this would have elevated efficiency estimates. However, mean efficiency estimates in the dive survey were relatively stable after five tows, indicating that our level of replication and area coverage was adequate. Another possibility is that the diver survey was less than 100% efficient, which also would have elevated dredge efficiency estimates. Dive surveys are generally considered to be the most efficient method for assessing scallop populations (Mason et al. 1979, Coleman 1998), so it is not really possible to test their efficiency. In this study each diver carefully surveyed transects only 1.75m wide in underwater visibility of at least 3m. We are therefore confident that the dive survey was very close to 100% efficient, at least for scallops greater than 90mm SL. It is possible that we underestimated the number of scallops less than 90mm SL (see below), but this would only have changed our efficiency estimate of 3% for this size class to a lower value and would not have altered the conclusions of the study. Finally, differences between the two methods could have been due to variation in substrate type between the two study sites, although given their similarity and close proximity this is unlikely.

The efficiency of scallop dredges is inherently variable (Dare et al. 1993). Therefore, for the purpose of stock assessment a mean of the efficiency estimates from the two methods is probably most appropriate. The differences between them (approximately 10%) could be built in as an error term when calculating population densities. Again it must also be emphasized that these efficiency estimates are only really applicable to fishing grounds of a substrate type similar to that examined in this study. Some of the fishing grounds around the Isle of Man are much more sandy than the study site, while others are stonier. Ideally, efficiency experiments will be repeated on those other grounds in the near future.

In common with many other studies of dredge selectivity (Chapman et al. 1977, McLoughlin et al. 1991, Dare et al. 1993), we found spring-toothed scallop dredges to be very selective toward larger scallops. Dredges almost completely missed scallops below 90 mm SL, although in contrast to some other studies (e.g. Mason et al. 1979, Dare et al. 1993) there were no significant differences between the efficiency of the dredges for the two larger size classes (90-109mm and 110mm + SL). The implications of this selectivity for stock assessment can be seen from Figure 2. On the basis of the dredge survey, the population appeared to be dominated by 3-year-olds (100-109 mm), while in reality 2-year-olds (80-89 mm) were much more abundant. Not surprisingly, the dredge survey did not catch many 1-year-old scallops either, but these were also rarely seen in the diver surveys. This could be due to poor recruitment in the previous year, but may also be due to their low visibility on the seabed (pers. obs). Diver surveys may therefore only be fully effective for *P. maximus* of two years or older.

For two of the by-catch species, *Cancer pagurus* and *Luidia ciliaris*, efficiency estimates from the depletion experiment were more than twice those from the diver surveys. This was a surprising result, until the effect of scallop dredging on the indirect mortality of by-catch species was considered (see also McLoughlin et al. 1991). As an extension of this study, damage to benthic organisms which encountered dredges without being captured, was also examined (Jenkins et al. 2001). On the basis of that study, 56% of *C. pagurus* left in the dredge tracks were expected to die (or be eaten) within a day of dredging (see also Hill et al. 1996, Veale et al. 2001). The respective figure for *L. ciliaris* was 31%. If it is considered that these additional individuals were effectively removed by dredging, values for total fishing mortality (catch plus indirect mortality) can be calculated. These work out as 67.0% for *C. pagurus* and 44.8% for *L. ciliaris*, very similar to the estimates of efficiency from the depletion experiment (68.5% and 47.5%, respectively). For the third species *Porania pulvillus*, none of the individuals left in the dredge track were expected to die (Jenkins et al. 2001). In this case, however, estimates from the depletion experiment and diver surveys were relatively similar (21.4% compared to 16.3%). Unlike the diver survey, the depletion experiment incorporated indirect fishing mortality into estimates of efficiency by measuring the decline in the abundance of live animals over the course of the study (10 days). It was therefore deemed appropriate to compare total fishing mortality from the diver surveys with estimates of efficiency from the depletion experiment. Indirect mortality would have had little effect on the depletion experiment results for *P. maximus*, as only 5% of individuals left in the dredge track were expected to die. The inability to calculate efficiency from the depletion experiment for the fourth by-catch species, *Asterias rubens*, was probably due to this species' high mobility and tendency to aggregate on dredge tracks (Kaiser and Spencer 1996, Ramsay et al. 1998, Veale et al. 2000a).

In summary, this study found that both depletion experiments and diver surveys of dredge tracks were effective for assessing scallop dredge efficiency. Differences between the results from the two methods were probably due to the inherent variability of dredge efficiency and emphasize the need for error terms to be built into efficiency estimates. The depletion experiment was more cost-effective (in terms of person hours) than the diver surveys, but provided little information on dredge selectivity. We therefore suggest that a combination of approaches is probably most appropriate.

ACKNOWLEDGMENTS

This study was supported by the Department of Agriculture, Fisheries and Forestry of the Isle of Man Government and the EU project ECODREDGE (FAIR CT98-4465). Many thanks to the boat crews of the RV Roagan (P. Crebbin, R. Georgeson and R. Gillam and G. Heaney) and RV Sula (R. Johnson and D. Kneen) and the many divers (M. Bates, C. Bradshaw, P. Collins, M. Mosley, C. Mullens, L. Patchell, K. Ross, T. Szebeni and L. Veale) and onboard scientists (R. Blyth, S. Buttle, G. Hughes, C. O'Donnell and T. Savage) who made the study possible.

PROBLEMS, PREDATORS, AND PERCEPTION: MANAGEMENT OF QUAHOG (HARDCLAM), *MERCENARIA MERCENRIA*, STOCK ENHANCEMENT PROGRAMS IN SOUTHERN NEW ENGLAND

WILLIAM CAMERON WALTON[1,*] AND WILLIAM CHARLES WALTON[2]

[1]*Horn Point Laboratory, University of Maryland, Cambridge, Maryland 21613;* [2]*Walton Research, Inc., 125 Turtleback Road, Califon, New Jersey 07830*

ABSTRACT Throughout southern New England and Long Island Sound, northern quahogs (*Mercenaria mercenaria* Linne), support large commercial and recreational fisheries. Municipal managers implement a number of tools to maintain the public stock, including enhancement with hatchery-reared juveniles, or seed. In 1999, we surveyed 68 municipal managers in the region (59 in Massachusetts and 9 from Long Island, New York) to identify the extent and magnitude of current programs and any obstacles to the success of such programs, specifically including predation. Of the 36 responses, 23 had used or were using *M. mercenaria* seed, planting an average of 1.4 million seed (± 355,000) at an average shell length of 15.9 mm (± 1.4) on a variety of substrates. Estimates of seed loss in the first year varied widely, but averaged 44% (± 6.2). Estimates of survival to market size were significantly higher ($P = 0.023$) in Massachusetts (49% ± 8.5) than New York (25% ± 4.0), the only significant difference between the two states. Losses were attributed to a variety of factors, but all respondents indicated predation was a major cause of that loss. Of predators identified as threats to *M. mercenaria* public seeding, green crabs, *Carcinus maenas*, were cited most frequently and scored as very serious predators (8.3 on a scale of 1 to 10 with 10 being the most damaging); other crabs, starfish, and gastropod predators were also perceived as serious threats. Managers were divided evenly on the effectiveness of predator trapping in reducing predator populations either within or among years in an attempt to protect seed. Our survey identified several areas where additional scientific study would benefit these municipalities: (1) assessment of seed survival to market size; (2) experimental demonstration of predators responsible for losses; and (3) evaluation of the effectiveness of trapping in both reducing predator populations and protecting seed.

KEY WORDS: public stock enhancement, *Mercenaria mercenaria*, *Carcinus maenas*, quahog, hardclam

INTRODUCTION

Throughout southern New England and Long Island Sound, northern quahogs, also known as hard clams (*Mercenaria mercenaria* Linne), support large commercial and recreational fisheries; for example, the commercial harvest in New York was over $17 million per year from 1995 to 1999 (pers. comm., National Marine Fisheries Service, Fisheries Statistics and Economics Division, Silver Spring, MD). Management of these fisheries, although subject to state and federal restrictions, is primarily carried out by municipal programs, which implement a variety of management tools to maintain the resource.

One strategy available to resource managers is to supplement the existing wild stock with hatchery-reared juvenile "seed" supplied by commercial and public shellfish hatcheries. Planting seed on public grounds may enhance the fishery directly, by introducing clams that survive and grow to a legally harvestable size, and indirectly by increasing larval supply and subsequent year classes. A more subtle benefit may be a dependable interannual supply of littlenecks and cherrystones, the two smaller and most valuable market size categories. Despite these possible benefits, quantitative tests of the success of such efforts are rare even in the largest, most ambitious programs (e.g., Macfarlane 1998). Predation, in particular, is recognized as a factor that may dramatically limit success of public seeding programs of various invertebrate species (e.g., Stoner & Davis 1994, Peterson et al. 1995, Barbeau et al. 1996). Similarly, predation is considered a major obstacle to success of private aquaculture of *M. mercenaria* in the northeastern portion of the United States (Spatz et al. 1996).

Despite this lack of quantitative evidence of benefits and concerns about predation, this method of stock enhancement has been widely adopted in the region, largely based on the qualitative perception that seeding benefits the fishery. Notably, the high incidence of the hatchery-reared subspecies *M. mercenaria* var. *notata* (which has a distinctive zig-zag shell coloration) in the catch is often cited by proponents of the method as evidence of success (W. Cameron Walton, pers. comm.).

Although the authors encourage a long-term rigorous assessment of the success of these public seeding programs, the reality is that many of these programs are driven by the perceptions of the local managers. Such perceptions are important not only because they steer management, but because they reflect many combined years of natural history observation and field work. In our study, therefore, we surveyed municipal shellfish managers throughout Massachusetts and Long Island, New York to: (1) describe the extent and nature of current municipal seeding programs; (2) identify potential losses of seed; and, in particular, (3) determine the extent and nature of loss of seed to predation.

METHODS

Our three-page survey (Appendix A) consisted of four sections: use of hatchery-raised *M. mercenaria* seed; handling of seed; losses of seed; and predation. Most questions were multiple-choice or required a quantitative answer. We indicated that survey participants would remain anonymous in the analysis of results. Draft versions were pilot tested with several shellfish constables on Martha's Vineyard, MA.

We mailed the survey on April 30, 1999 to all of the 59 Massachusetts shellfish constables listed with the Massachusetts Division of Marine Fisheries. One month later, we sent a duplicate of the survey with a second request to nonrespondents. Finally, two months later, we called nonrespondents requesting the return of a completed survey.

In response to inquiries from municipal shellfish managers on Long Island, NY, on December 6, 1999, we sent surveys to nine municipal shellfish managers, whose names were provided by G. Rivarra of the Cornell Cooperative Extension. Unlike the Massachusetts recipients, the New York recipients were clustered geographically (toward the eastern end of the island). Follow-up requests were handled as they were with Massachusetts recipients.

In compiling results, some responses were simplified or standardized. For example, an estimated loss of 40–60% of planted seed was reduced to the median of 50%. In addition, if seed size was given as mesh size, we converted this to an average shell length. For identification of predators and their perceived effect, we asked respondents to list up to five of the worst predators upon seed. To quantify the threat posed, we asked further for respondents to score each predator with a number from 1 to 10, with 10 indicating that the predator was capable of inflicting severe losses. To capture both frequency of listing and perceived magnitude of the threat, we weighted each predator "vote" by its quantitative rating to derive a summed score. To test for differences between states, we conducted paired *t*-tests, assuming unequal variances between the populations with a Bonferroni adjusted probability.

RESULTS

Survey Response

Of the 68 surveys mailed, 36, or ~53%, were completed and returned. Of these responses, 23 respondents had used hatchery-reared seed as a stock enhancement tool, of which only one Massachusetts respondent had discontinued use after 1995. All nine respondents in New York currently use hatchery seed, and 13 of the 27 Massachusetts respondents currently seed. Several negative respondents (those who responded but indicated no current or past use of seed) indicated that their local shellfish beds were closed because of pollution, so they were implementing no stock management programs; whereas, two others expressed interest in implementing seeding in their municipalities.

Use and Extent of Hatchery Seed

Among affirmative respondents (Table 1), managers have used seed on average for 12.6 years, with no difference between states ($P = 0.99$). On average, Massachusetts municipalities received just under one million seed; whereas, New York municipalities received closer to two million, although this was not significantly different ($P = 0.194$). Programs varied widely in magnitude, from 50,000 to six million seed received in the most recent year. Typically, the size of the seed upon receipt was 5.2 mm in shell length (± 1.12, $n = 21$), with no difference between states ($P = 0.512$). Most respondents received seed in late spring/early summer.

Although two New York municipalities planted the seed immediately upon receipt, most managers maintained the seed for additional grow out, placing the seed in trays, rafts, or upwellers to obtain additional growth and protect them from predation. Seeding typically occurred when the seed were 15.9 mm (± 1.44, $n = 22$). Planting of these seed occurred from August to November. Several managers noted that they would occasionally receive seed in the fall and plant these directly. In addition, several managers based time of planting on the size of the seed; one constable in Massachusetts would keep small seed under netting through the winter to allow an additional year of growth before planting. Most planted the seed on unvegetated sand, mud, or muddy sand substrate (Fig. 1), although gravel and vegetated bottom were occasionally used.

Losses of Seed

Managers estimated that they lost 44% of planted seed within the first season (Table 1), with no significant difference between states ($P = 0.225$). Notably, estimates of first year loss ranged from 9 to 90% and tended to be lower in Massachusetts than New York ($P = 0.225$). Based on their observations, every respondent using seed indicated that predation was a major cause of that loss (Fig. 2). Losses attributable to the stress of handling and dispersion by currents were also cited; whereas, theft by private individuals was discounted as a potential source of loss (Fig. 2). Additional suggested sources of loss were: freezing temperatures (two respondents); the quahog parasite QPX (one respondent); and damage from raking (one respondent). There was no relationship between planting size and estimated first year mortality (Fig. 3). Despite these initial losses, managers estimated that 39% of planted seed survived to market size (Table 1). New York respondents, however, estimated a significantly lower survival rate of seed to market size than their Massachusetts counterparts ($P = 0.023$); 25 versus 49%, respectively. As with estimates of first year loss, estimates of survival to market size ranged widely, from 5 to 90%. Of those

TABLE 1.

Description of municipal *Mercenaria mercenaria* seeding programs in Massachusetts (MA) and New York (NY).

Factor	MA	NY	*P*	All Responses Combined
Years of use	12.6 (± 2.40, $n = 13$)	12.7 (± 1.55, $n = 9$)	0.986	12.6 (± 1.52, $n = 22$)
Quantity of seed received last year	994,429 (± 422,906.2, $n = 14$)	1,988,111 (± 598,288.4, $n = 9$)	0.194	1,383,261 (± 354,898.6, $n = 23$)
Average seed size upon receipt (mm)	4.6 (± 1.42, $n = 14$)	6.2 (± 1.85, $n = 7$)	0.512	5.2 (± 1.12, $n = 21$)
Average seed size upon planting (mm)	16.7 (± 2.35, $n = 13$)	14.8 (± 1.05, $n = 9$)	0.477	15.9 (± 1.44, $n = 22$)
Loss of seed upon planting	39.3% (± 7.91, $n = 13$)	54.6% (± 8.95, $n = 6$)	0.225	44.2% (± 6.19, $n = 19$)
Survival of seed to market size	48.6% (± 8.48, $n = 11$)	24.6% (± 4.03, $n = 7$)	0.023	39.3% (± 6.01, $n = 18$)

Each table value is followed by one SEM and the responding sample size.
The *P*-value indicated is the Bonferroni adjusted probability of differences between states.

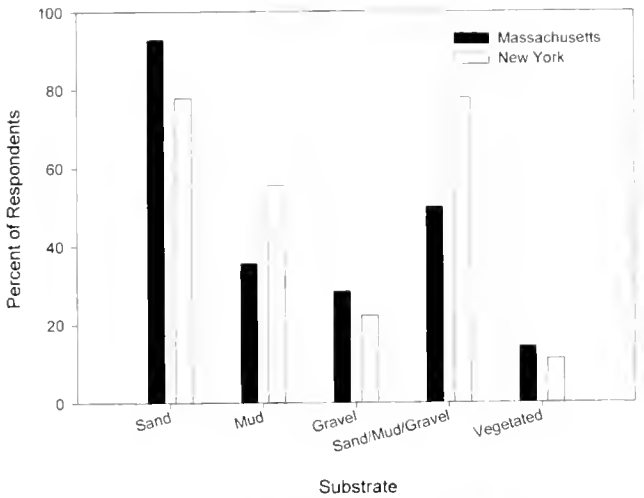

Figure 1. Use of various substrates for seeding of *Mercenaria mercenaria* by municipal programs in Massachusetts and New York.

managers planting seed < 25 mm shell length, there was a significant positive correlation between the average size of planting and the estimate of survival to market size ($P = 0.046$), excluding one outlier (Fig. 3).

Identifying and Controlling Predation on Seed

Many of the users of seed took measures to protect their seed from predation both before planting (85%, $n = 20$) and after planting (50%, $n = 22$). Predominantly, managers used mesh and netting to keep predators away from seed; a subset used traps in an effort to reduce the abundance of various predators. Of those who took any measures to protect seed, 62% felt that their efforts had had some success increasing seed survival, 14% felt that they had made efforts without much success, and 24% indicated that they had made no efforts. In addition, 46% of respondents had tried and given up various methods of protecting seed. Abandoned methods included: various barriers (nets, rafts, etc., $n = 5$), altered fishing practices (overwintering, closed areas, $n = 2$), direct predator reduction by trapping ($n = 2$), and biological control ("guarding" seed with toadfish, *Opanus tau*, to deter crab predation).

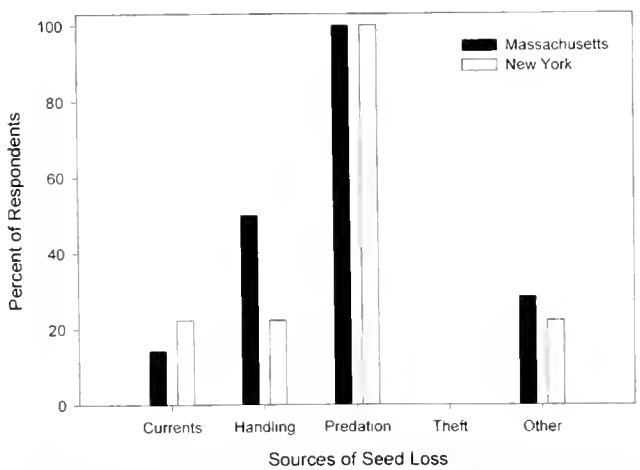

Figure 2. Various perceived sources of loss of *Mercenaria mercenaria* seed by municipal programs in Massachusetts and New York. See text for explanation of "other" sources of loss.

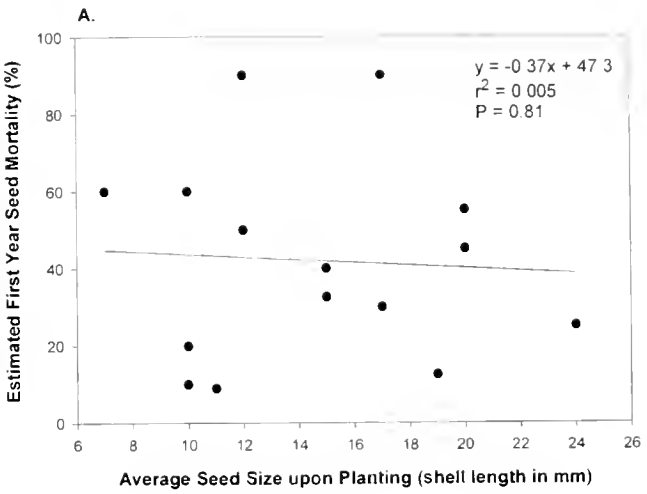

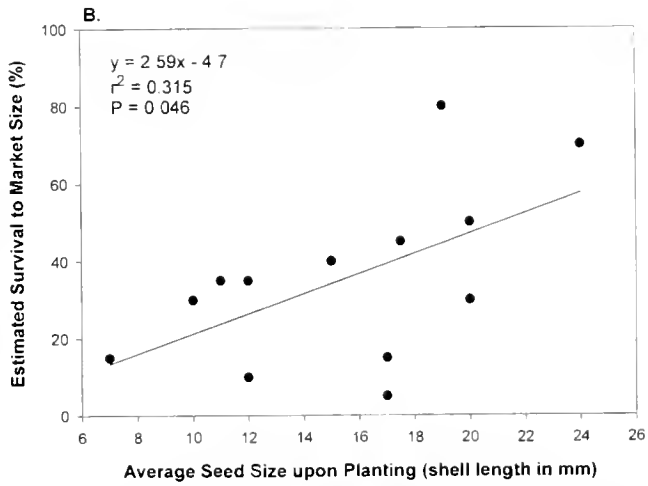

Figure 3. Relationship between average size of planting and A) estimated first year losses ($n = 15$) and B) survival to market size ($n = 13$) of *Mercenaria mercenaria* seed.

A wide variety of predators were recognized as threats to the success of municipal seeding programs (Fig. 4). Of the noted predators, green crabs (*Carcinus maenas*) were mentioned most often (15 of 22 respondents) and were considered capable of inflicting very serious losses (receiving an average score of 8.3 out of 10). Whelks (*Busycon carica* and *B. canaliculatus*) received the second highest summed score, which was approximately half the score of *C. maenas*. Two other portunid crabs were considered serious threats as well: the calico, or lady, crab (*Ovalipes ocellatus*) and the blue crab (*Callinectes sapidus*). Other predators considered serious threats by many respondents were (in order of scored importance): mud crabs (various xanthiid crab species), unspecified "crabs," starfish (*Asterias forbesi*), horseshoe crabs (*Limulus polyphemus*), spider crabs (*Libinia dubia* and/or *L. emarginata*), muricid drills (presumably *Eupleura caudata* and/or *Urosalpinx cinerea*), and sea gulls (various *Larus* spp). Other predators were noted by only one or two respondents, such as toadfish (*O. tau*), eels (presumably *Anguilla rostrata*), seals (presumably *Phoca vitulina*), sponges (unspecified *Cliona* spp.), and humans (*Homo sapiens*). Note, however, that only a single respondent listed rock crabs (*Cancer irroratus*) but gave them the highest

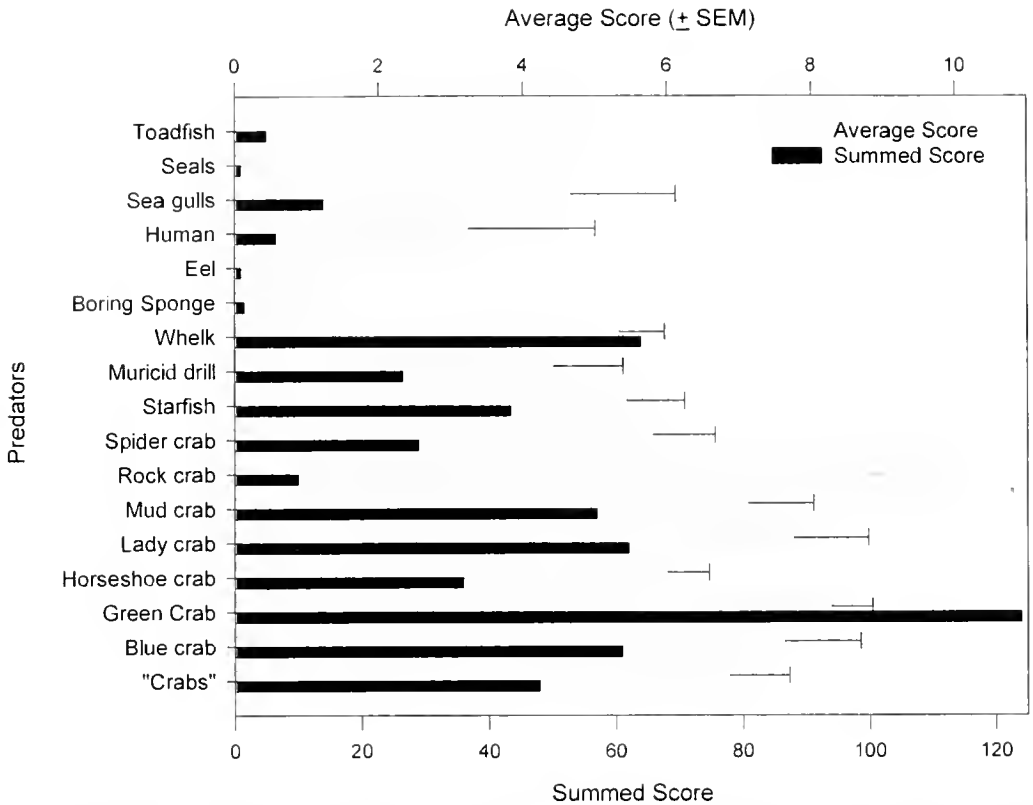

Figure 4. Perception of threat posed by various predators to the success of *Mercenaria mercenaria* municipal seeding programs in Massachusetts and New York. Predators were scored from 1 to 10, with 10 being the worst. Summed scores were derived by adding each of the scores together, reflecting both perceived threat and frequency of citation. See text for scientific names of species.

score possible, indicating the local importance of that particular predator.

Most managers (81%, $n = 21$) had noted changes in the predator community. Although responses varied, 10 respondents had observed a change in the crab community; of these, one had noted a decrease in green crabs, one indicated that the number of crabs varied, and eight had seen an increase in various portunid crabs. Conversely, six respondents had observed a change in the abundance of starfish; of these, one indicated an increase, one indicated that the population varied, and four had seen a decrease in starfish. Last, gastropod predators were seen to increase by two respondents.

In an attempt to reduce losses to predation, most respondents (65%, $n = 23$) had attempted or were currently trapping predators. Based on this experience (Table 2), almost half (44%, $n = 9$) of Massachusetts respondents felt that trapping noticeably reduced predator abundances across a season; whereas, most New York managers (75%, $n = 4$) observed intra-annual reductions. Fewer managers had opinions about the interannual effectiveness of trapping ($n = 10$), perhaps reflecting uncertainty. Of those who responded, respondents' opinions reflected the intra-annual perceptions; three of seven Massachusetts managers and two of three New York managers noted interannual reductions in predator abundance because of trapping. Those who supported trapping noted clear reductions in the abundance of the predators, and several were increasing the magnitude of their program. Those who did not trap or had given it up expressed various concerns, including: attraction of predators to the area, the large acreage involved, negative effects on nontarget species, including endangered species and a general sense of ineffectiveness (as one respondent wrote, "One can not defeat Mother Nature"). Two respondents specifically indicated a need for a test of the effectiveness of trapping before they could answer the question.

TABLE 2.

Perceived effectiveness of trapping in reducing predator populations by municipal *Mercenaria mercenaria* seeding programs in Massachusetts (MA) and New York (NY).

Factor	MA	NY	All Responses Combined
Observed intra-annual reductions	44.4% ($n = 9$)	75% ($n = 4$)	53.8% ($n = 13$)
Observed interannual reductions	42.9% ($n = 7$)	66.7% ($n = 3$)	50% ($n = 10$)

DISCUSSION

We were struck by both the response and degree of interest in regional public seeding of *M. mercenaria* var. *notata*; over half of the managers that were mailed surveys completed and returned the survey, an unusually high response rate in mailed surveys. Not surprisingly, a large percentage (64%) of those responding used seed to enhance their municipal stocks of *M. mercenaria*. If we conservatively assume that nonrespondents had not used seed, then approximately one-third of those municipalities surveyed (23 of 68) use or have used hatchery-reared seed; we know this to be an underestimate, because at least two municipalities that conduct

seeding did not complete their surveys (W. Cameron Walton, pers. comm.). Based on several notated answers, many respondents who did not use *M. mercenaria* seed did so because their shellfish beds were closed and/or inappropriate for raising quahogs (e.g., many areas north of Cape Cod). Several nonusers, however, expressed interest in initiating seeding programs. Of those responding and conducting seeding, many expressed interest both in the results of the survey and additional sources of information as a means of improving their programs.

Managers recognized a variety of factors that limit success of their seeding programs. All, however, agreed that predation was a causal factor (Fig. 2). Despite attempts by most managers to increase seed survival by growing seed to a larger, and, therefore potentially less vulnerable, size, estimates of losses of seed upon planting varied widely but averaged 44% (Table 1). Interestingly, although there was no relationship between average planting size (< 25 mm shell length) and perceived losses in the first year, there was a significant increase in perceived survival to market size with increasing planting size (Fig. 3). This lack of agreement in estimates suggests that either most losses occur after the first year (thus producing the positive correlation between planting size and survival to market size) or that managers have difficulty estimating first year survival. Because much ecological literature indicates the importance of prey size in determining prey vulnerability to crabs (see Juanes 1992 for a review), it seems likely that managers have not observed a positive relationship between planting size and first year survival simply because it is difficult to measure.

Between the states, there was a trend toward lower estimates of first year seed loss and significantly higher estimates of survival to market size in Massachusetts relative to New York (Table 1). Whether this difference reflects real differences in the field (e.g., the predator community, water quality) or between the attitudes of managers is unclear, but highlights the need for repeatable, rigorous field assessment of survival.

The identification of particular predators varied widely among responses, reflecting in part the temporal and spatial variation of predator populations (Fig. 4). Despite this variation, green crabs (a nonindigenous species originally from Europe) were cited by the largest number of respondents and were considered a very serious threat by most, receiving the highest summed score by far. Crabs, in general, were recognized as major predators, as were starfish and predatory gastropods. Interestingly, almost all respondents who commented upon changes in crab populations had observed an increase in portunid crabs, potentially increasing the perception of damage done by these species.

Despite agreement upon both the importance of predation and the green crab as the most damaging predator, municipal managers were divided on the effectiveness of predator trapping, including a number who were unable or unwilling to assess trap effectiveness. Of those who expressed an opinion on the success of trapping either within or across years, about half found trapping effective. There was a tendency (Table 2) for New York managers to find trapping more effective than their Massachusetts counterparts, despite the countertendency for New York managers to perceive higher losses of seed (Table 1). This suggests several competing alternatives: (1) trapping may reduce predators but not increase seed survival; (2) trapping may reduce predators but absolute losses to predation are greater in New York municipalities; or (3) despite managers' perceptions, trapping does not noticeably reduce predators. The first alternative could be generated by several mechanisms: low seed survival despite trapping could be caused by factors other than predation, trapping of a predator other than the one responsible, and/or compensatory predation (either intra- or interspecific) after removal of the primary predator. The second alternative could be tested by conducting prey outplants in both regions to determine relative predation pressure. The last alternative requires a rigorous field test of the efficacy of trapping as a predator control technique.

Are the current seeding programs large enough to be economically significant within the region? Responding managers planted just under 32 million seed in the year immediately before receiving the survey. A very rough calculation of the relative importance of seeding upon *M. mercenaria* fisheries in these two states can be obtained by making various assumptions about survival and market prices. Based on the Massachusetts estimates of seed survival to market size (49%), approximately 6.9 million of the 14 million planted seed would survive to market size. If most of these are caught (80% given that their locations are known) during the first year of obtaining legal size, 5.5 million would be harvested. At a market price estimated $0.20/clam, municipalities might expect to generate ~$1.1 million by seeding (without considering any benefits of such stock enhancement upon subsequent recruitments). In New York, on the other hand, the lower estimate of survival to market size (25%) means that only 4.5 million of the 18 million planted seed would survive to market size. Making similar assumptions about harvesting and price, 3.6 million quahogs would be harvested in the first year, yielding a value of ~$720,000. Many of these seeded clams, however, may be harvested by recreational fishermen, and, thus, do not contribute directly to the regional economy. In addition, such calculations do not take into account any indirect benefit of seeding upon population abundance via reproduction.

In conclusion, municipal managers who have adopted seeding as a management tool recognize a variety of factors that limit survival of seed. Despite these losses, which vary in space and time even within a municipality, managers who used seed expressed strong belief in the effectiveness of seeding. The results of this survey suggest, however, several areas in which managers would benefit from additional information. First, programs would benefit from a quantitative assessment of survival of seed to market size, allowing a more accurate assessment of the worth of such enhancement efforts. Second, it is essential to determine experimentally the most important predators upon *M. mercenaria* seed to ensure that any predator removal efforts are targeting the correct species. Last, managers need an evaluation of the effectiveness of trapping. Managers themselves are unsure as a group, and, furthermore, the discrepancy between estimated seed survival and trapping effectiveness by New York managers suggests an area worthy of investigation.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the time and effort volunteered by the municipal shellfish managers to complete the surveys. In addition, V. S. Kennedy and an anonymous reviewer provided numerous helpful comments and suggestions.

Appendix A

Southern New England & Mid-Atlantic Shellfish Management Survey: Use of Hatchery-Reared Quahogs

Please fill out and return in the SASE provided, or mail to Bill Walton, Beals Island Regional Shellfish Hatchery, PO Box 83, Beals, ME 04611

I. Use of Quahog Seed

Do you (or your town) currently, or have you in the past, used hatchery-raised quahog seed to enhance your fishery?

___ Yes, currently use seed (indicate number of years in use ___)

___ Yes, used seed in the past but have stopped (indicate last year used 19__)

___ No, never used quahog seed (You have completed this survey and thank you for your participation. PLEASE RETURN THIS IN THE SASE)

II. Handling of Seed

1. In the last season you used seed, what was the approximate quantity of seed you received and/or produced?

_____

2. In the last season you used seed, what was the average size (shell length or mesh size) of the seed when you received it?

__ mm or mesh size

3. In the last season you used seed, what was the average seed size when you planted them out?

__ mm or mesh size

4. What is a rough time line of quahog seed in your possession in a typical year (for example, get seed in July and plant immediately, or get seed in July, put in floating rafts until October, and then plant out)

_____

_____

5. What type or types of bottom do you plant out on? (Check all that apply)

___ Sand ___ Mud ___ Gravel ___ Sand/Mud/Gravel Mix ___ Vegetated

III. Loss of Seed

1. What percent (estimated) of the seed you've planted out during a typical season did you lose?

   ___ %

2. What were the main causes of that loss?

   _ Normal effects of transportation/handling Theft

   _ Washed away by currents Predation

   _ Other (please specify) _____

3. In your overall experience, estimate typically what percent of seed you plant out makes it to market size in your town.

   ___ %

IV. Controlling Predation on Seed

1. If you did not immediately plant out the last seed you received, what attempts, if any, did you make to protect them from predation prior to planting?

   _____

2. Once you planted out your last seed, what attempts, if any, did you make to protect those seed from predation?

   _____

3. Please identify up to the 5 worst predators of your seed and enter them below. For each predator you mentioned, please rate it as a threat to your seed (10 = capable of inflicting severe losses upon seed; to 1 = very little threat).

   Predators: _____ Rating (10 to 1):

   Worst: _____ _____

   2nd worst: _____ _____

   3rd worst: _____ _____

   4th worst: _____ _____

   5th worst: _____ _____

4. Have you made any efforts to protect seed that have significantly increased seed survival?

___ Yes, have had some success ___ Made efforts without much success

___ No efforts made and or required

5. Are there any methods of protecting seed that either you or your town's prior constables tried but gave up? If so, what were they, and why were they given up?

No

__ Yes (please specify methods and reason for giving them up)_____

_____

6. Have you noticed any changes in the predator community in your local waters (for example, have starfish increased dramatically over the last decade)?

___ No

__ Yes (please specify those changes)_____

_____

_____

7. Among other things, I'm gathering information on the effectiveness of predator trapping. If you have trapped, or currently do so, do you think it noticeably reduces the predator population you're trapping either:

a) across a season ___ Yes ___ No

b) over consecutive years ___ Yes ___ No

Please comment on your experience with trapping predators to protect shellfish, in particular quahog seed.

_____

_____

You have completed the survey. Thank you very much for your assistance with this matter. Please return the survey in the provided envelope. I will be glad to make the results of the survey, as well as results of my research into ways of improving seed survival, to all respondents. If you would like to receive this information, please include your business card or your name and address on a separate sheet of paper. Again, thank you for your time and assistance.

EFFECTS OF CAGING ON RETENTION OF POSTLARVAL SOFT-SHELLED CLAMS (*MYA ARENARIA*)

LARA K. GULMANN,[1] LAUREN S. MULLINEAUX,[1] AND HEATHER L. HUNT[2]

[1]*Biology Department, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543;*
[2]*Institute of Marine and Coastal Sciences, Rutgers University, New Brunswick, New Jersey 08901*

ABSTRACT Postlarval transport is an important process affecting the population dynamics of many coastal benthic species. The first growth season after settlement represents one of the most influential life-history stages of many benthic species, including the commercially important soft-shelled clam *Mya arenaria*. In the present study, the effect of a mesh cage on the retention of postlarval soft-shelled clams was investigated using a laboratory flume. Three size categories of clams were exposed to a range of velocities both with and without the cage. The presence of the cage did not significantly increase the number of clams retained for most clam sizes and velocities tested. Only at the fastest velocity tested did the cage significantly increase the proportion of clams retained. Characterization of flow patterns indicated that flow velocities were reduced inside the cage at the fastest velocity but not at the lower velocity. We propose that the cage effects on retention are negligible in flows up to a critical velocity, above which they protect clams from resuspension. These results can be applied to field applications of mesh cages to optimize the beneficial caging effect.

KEY WORDS: *Mya arenaria*, postlarvae, cage, transport, resuspension, shear velocity, flume

INTRODUCTION

Harvesting of the soft-shelled clam, *Mya arenaria* L., is an important commercial industry along the coast of New England. Adult *M. arenaria* are collected from hundreds of coastal embayments from Canada to Cape Hatteras, producing a total annual revenue in excess of $12 million (U.S. Fisheries Report 1998). Yet the productivity of soft-shelled clam fisheries is erratic because *M. arenaria* recruitment is subject to extreme temporal and spatial variability (Beukema et al. 1978, Möller and Rosenberg 1983). Because adult population density is linked to recruitment, this variability results in dramatic population changes from season to season and among locations within the local habitat.

The observed variability in recruitment could result from changes in any one or more of the numerous processes operating on larval and postlarval stages. Local recruitment is a result of the following: initial larval supply, proportion of larvae that settle, post-settlement mortality due to predation and/or inadequate resources, and post-settlement transport processes. Although numerous studies have investigated the factors controlling initial larval settlement and mortality (Pfitzenmeyer 1962, Günther 1992, Rodriguez et al. 1993), few have examined the effects of hydrodynamic transport of postlarvae (Emerson and Grant 1991). Both physical processes and behavioral responses, such as depth of burrowing and byssal drifting, contribute to postlarval transport of recruits (Sigurdsson et al. 1976, Newell and Hidu 1986). In addition, over the first growth season, changes in size and burial depth could affect the proportion of clams retained in particular flow regimes. The physical parameter most relevant to hydrodynamic transport of recruits is bottom shear stress, because it controls the suspension and deposition of particles. Shear stress is defined as shearing strain caused by water moving over the bottom and is proportional to the rate of deformation of the fluid (Gerhart and Gross 1985).

In response to the high variability in *M. arenaria* recruitment, some fisheries have implemented programs to increase settlement and decrease resuspension of either "wild" postlarvae or cultivated spat by manipulating benthic conditions. One of the most successful techniques involves placing mesh netting (cages) over the sand flats to alter the hydrodynamics and exclude predators (Beal 1993, Marcotti and Leavitt 1997). Although the beneficial role of predator and disturber exclusion has been demonstrated (Beal 1993, 1994, Dunn et al. 1999), little is known about the mechanisms by which cages may alter the hydrodynamic regime and allow for enhanced population densities.

The goal of the present study is to quantify the effect of caging on the following: near-bottom flow characteristics and postlarval clam retention over a range of clam sizes and benthic shear stresses (as quantified with shear velocity u_*). We use a recirculating flume to simulate tidal flows common in the field and to quantify the effect of the cage on clam retention in a test bed of sediment. We define retention as the proportion of clams not eroded from the sediment in the presence of flow and resuspension as the quantity of clams eroded from the sediment and transported downstream. We focus on resuspension because of its relevance to natural situations where clam larvae or postlarvae dropped from suspension and settled in quiescent periods of a tidal cycle, but are subjected to resuspension during vigorous periods of flood and ebb. The flume studies also are relevant to aquaculture situations where clam spat are seeded at low tide and exposed to suspension during subsequent tidal excursions. Our research addresses the following questions:

How does the cage affect near-bottom velocities and turbulence in the flume?
How does the cage affect postlarval transport and retention of *Mya arenaria*?
How do these caging effects vary with clam size (i.e., for recruits during their first growth season) and with flow velocity (i.e., over a range of realistic shear stresses) from a tidal environment?

We expect the cage to alter near-bottom flows by reducing the benthic shear stress under the structure. For a specific clam size, this reduction in shear stress should result in a reduction in numbers of clams resuspended, at flows that typically would erode uncaged buried clams. Because higher shear stresses typically are

required to resuspend larger clams (Emerson and Grant 1991, Dunn et al. 1999), it is important to conduct our flume studies over a range of clam sizes and flow speeds, in order to provide results that can be generalized to the field.

This study is intended to provide a mechanistic understanding of how mesh caging influences resuspension of *M. arenaria*, which represents a potentially important loss to a local population. By focusing on this mechanism, we leave unexplored other potential cage effects such as those on larval settlement and deposition; mortality due to predation; and enhancement or depletion of food supply. However, a characterization of the flow alterations caused by caging provides a reference point for predictions of other hydrodynamically-controlled processes such as deposition and food flux.

MATERIALS AND METHODS

Test Organism and Sediment

Flume experiments were conducted in 1997 and 1998 to test the effects of caging on retention of three size- categories of clam recruits (corresponding to a progression of first season sizes of clams resulting from a late spring settlement in Barnstable Harbor, Massachusetts; data not shown) over a range of shear velocities. The shell length (SL) of the small, medium, and large size recruits was measured as 1.3 ± 0.17 mm (mean ± st. dev.; n = 100), 1.8 ± 0.15 mm, and 2.3 ± 0.3 mm, respectively. Flume studies were conducted in the summer of 1998 and spring 1999 to characterize flow along the flume and around the cage. Postlarval *M. arenaria* were acquired from Beals Island Regional Shellfish Hatchery, Beals, Maine in 1997 and from Mook Sea Farm, Inc., Walpole, Maine in 1998.

All clams were held in plastic containers with 64 μm mesh tops and supplied with 10 μm filtered, running seawater (~21°C) from Vineyard Sound. In 1997, clams were fed Tahitian *Isochrysis galbana* at least once a day, but cultures experienced higher mortality than expected. Thus, in 1998, the clams were fed twice a day with T. *Isochrysis galbana* and *Tetraselmis* sp. (both species from Instant Algae, Reed Mariculture Inc.) and aerated the holding containers to improve survival rates.

Sediment used for the experiments was collected from Barnstable Harbor. Only the surficial, oxic layer of sediment was used to avoid hydrogen sulfide toxicity and provide suitable substrate for the clams. For consistency among experiments, all sediment was passed through a 2 mm sieve and retained on a 180 μm sieve. Based on extensive sampling, over 65% of Barnstable Harbor sediment was within the 180 μm to 2 mm size range (dry wt. basis); therefore, this test sediment was a reasonable approximation of field conditions (authors' unpublished data).

Sediment was kept frozen at −4°C until use. After thorough mixing, defrosted sediment was placed in the sediment box and the surface was leveled. Prepared sediment had a median grain size of 150 to 180 μm.

Flow Characterization and Cage Setup

Experiments were performed in a recirculating flume at the Woods Hole Oceanographic Institution's Rinehart Coastal Research Center. The flume consisted of a 30 cm deep, 60 cm wide, and 17 m long channel through which water was circulated by an impeller pump (Butman and Chapman 1989). Flow was rectified at the headbox of the flume by a Plexiglas grid of 1.2 cm squares 7.5 cm long. At the very downstream end of the flume, an accordion weir set the area available for water outlet. Simultaneous alongstream and vertical velocities were measured by a two-axis Laser Doppler Velocimeter (LDV) (Trowbridge et al. 1989). Velocity profiles were measured 1.7 m upstream of the test section (Fig. 1). Shear velocities (u_*) were estimated from the flow profiles using an iterative method to calculate u_* in a steady, one-dimensional open-channel flow (Trowbridge et al. 1989). To ensure that the desired velocity was produced, water velocities were measured at 25 hertz and averaged over 4 minutes of measurements at each of 10 heights above the flume bottom (0.9, 1.2, 1.6, 2.1, 2.7, 3.4, 4.2, 5.0, 6.0, and 8.0 cm). These velocity profiles were conducted for all trials to estimate variation in flow among replicates for specific target velocities (target velocities ranged from u_* = 0.7–2.0 cm s^{-1}).

The working section of the flume was 12.5 m downstream from the water entrance. At this distance the turbulent boundary layer was fully developed. For these experiments, a section of the flume's bottom was replaced with a removable acrylic tray (55 × 55 cm) containing a central recessed sediment box (20 × 20 × 2 cm deep) (Fig. 1). The cage (described below) surrounded the sediment box and was secured to the acrylic tray. For each experiment, fresh sediment was placed in the box and the surface leveled before fitting the tray into the flume. The edges of the tray were flush with the flume bottom. The water depth in the flume was approximately 12 cm and water temperature was 20°C to 22°C. We selected a target water depth of 12 cm to maintain a water column width-to-depth ratio of at least 5, thereby maximizing the accuracy of the shear velocity measurements (Nowell and Jumars 1987, Butman and Chapman 1989).

In all experiments, flow was established by adjusting the pump speed and outlet weir setting to attain the target water depth (h = 12 cm at a distance of 21 cm upstream of the test section; Fig. 1) and target free-stream velocity (u_8 = free-stream flow at 8 cm above bottom measured 1.7 m upstream of the test section). Once the target velocity and depth were achieved (within 5–10 minutes of introducing the tray), velocity profile measurements were initiated. Velocity profiles were reproduced with only slight variation (<5%) among replicates for a single target velocity. Afterwards,

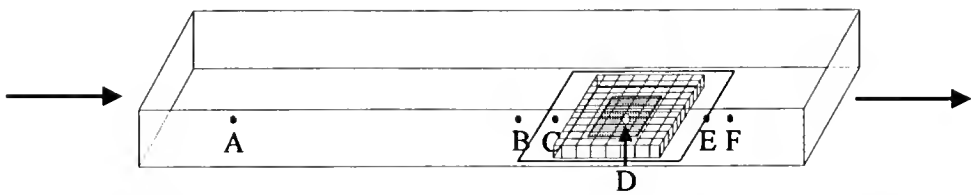

Figure 1. Oblique view of the test section of the flume showing the location of the cage and positions of velocity profile measurements. Respectively, A, B, and C are 170, 21, and 6 cm upstream of the cage front. D is 27 cm downstream from the leading edge of the cage. E and F are 10 and 20 cm downstream of the cage. Gray box within the cage represents the sediment box.

the flow speed was gradually reduced from the target velocity to u_8 = 3 cm s^{-1} and the tray was removed from the flume.

The cage used in these experiments was a 46 cm long × 54 cm wide × 5 cm high metal frame covered on the top and sides with plastic mesh netting of a size commonly used by aquaculturists and fishery managers (InterNet Inc. Minneoplis, MN; oriented flexible square; mesh size = 0.32 cm). In an ideal setup, the water depth should be at least 3 times the cage height in order to avoid generating free-surface interactions (Nowell and Jumars 1984). For our experiments, we were limited to a water depth of 12 cm and to a cage height of >4 cm to create adequate separation between the bottom of the flume and the roof of the cage. Although the flows above the cage were likely influenced by the structure's proximity to the free surface, the magnitude of this interaction, and its potential effect on bottom shear stress, were expected to be minor. This expectation was evaluated during the experiments using water height and velocity measurements. The cage support rods were positioned >5 diameters from the sediment box and had no detectable influence on water flow or sediment transport (Nowell and Jumars 1987).

At least one representative upstream shear velocity (u_*) was measured for each flow regime tested (Table 1). For most flow regimes, u_* was calculated during each experimental trial, and averaged across the 3 or 4 replicate trials to characterize the flow treatment (note values for u_* were not recorded in some trials due to technical problems). Shear velocities were selected to fall within the range of typical estuarine and bay flows, as derived from current meter data from Barnstable Harbor. At three sites in Barnstable Harbor, the range of velocities measured during a spring tide in 1998 corresponded to shear velocities of 0–3.8 cm s^{-1} and, over half of the time, flows were within the range used in these trials (0.7–2.0 cm s^{-1}) (authors' unpublished data).

Flow patterns around the cage were quantified by taking centered velocity profiles 6 cm upstream of the cage, mid-cage, and both 10 and 20 cm downstream of the cage (Fig. 1). Velocity profiles were also taken at these locations without the cage present. This array of profiles was conducted at shear velocities of u_* = 1.8 and 2.0 cm s^{-1}. These velocities were selected after conducting the clam retention trials, to investigate flow patterns at and below a shear velocity that yielded significantly greater clam retention in the caged treatment (See Results, Retention section). Flow deviations caused by the cage were quantified in the two flow regimes by calculating the time-averaged velocity at each measurement point and comparing the difference between the cage and no-cage profiles at both velocities. Fluorescein dye visualizations were performed to describe qualitatively the turbulence and flow separation generated by the mesh cage.

TABLE 1.

Mean alongstream velocities at 8 cm above flume bottom (u_8) and mean shear velocities (u_*) for all three clam sizes and flow treatments. Standard deviations are in parentheses.

Clam category	u_8 (cm s^{-1})	u_* (cm s^{-1})	n
Small	14.3 (0.3)	0.66 (0.01)	8
	30.1 (0.3)	1.30 (0.02)	8
Medium	32.6 (0.8)	1.41 (0.02)	4
	38.1 (0.5)	1.61 (0.02)	6
	40.1 (0.7)	1.73 (0.01)	6
	43.8 (0.4)	1.83 (0.01)	6
Large	47.2 (1.2)	1.97 (0.09)	6

Retention Trials

The main objective of the retention trials was to determine the effect of caging over a realistic range of field flows and first season clam sizes. Three or four replicate trials were conducted with and without the cage for each clam size over a range of selected velocities (n = 3 for all trials except when u_* = 0.7 and 1.3 cm s^{-1}). The small clams were exposed to shear velocities of 0.7 cm s^{-1} and 1.3 cm s^{-1}; medium size clams to 1.4–1.8 cm s^{-1}; and large clams to 2.0 cm s^{-1}. This experimental setup did not follow an ideal 3-factor design with caged and uncaged treatments in all combinations of flow speed and clam size for two reasons: the number of first season clams was limited and some data were incorporated from experiments conducted as a component of another study. The large clam data and part of the medium sized clam data (u_* = 1.4 and 1.6 cm s^{-1} trials) were gathered as part of a caging study we conducted in association with flume trials in Dunn et al. (1999).

In order to use the available clams most efficiently, we selected what we anticipated to be the most relevant flow speeds for each clam size. Lower speeds were used for smaller sizes because lower shear velocities were anticipated to erode smaller clams. The velocity ranges selected for each clam size were chosen based on preliminary flume experiments that determined the critical velocities needed for initial movement of sediment and clams, both buried and unburied. The lower velocities were selected to erode non-burrowing clams, but not significantly erode the sediment, while the higher shear velocities were intended to erode a portion of the sediment and thereby allow assessment of the burrowing clam's response to elevated flow.

For each retention trial, we selected 200 active clams. This number corresponds to a density of 5,000 clams per m^2 (within the 20 cm × 20 cm sediment box) and approximates actual Barnstable Harbor field densities (authors'unpublished data). The clams were suspended in seawater and then rinsed through a plastic cylinder (10 cm diameter × 20 cm high) held 1 to 2 cm above the sediment surface. Suspending the clams ensured that they were distributed evenly on the sediment. Use of the cylinder ensured that the clams settled onto the sediment box surface, not the acrylic perimeter. The clams were given 20 minutes to burrow (sufficient time for burial based on previous observations). After the burial time, the sediment tray was removed from the seawater table, the number of non-burrowing clams was recorded and those remaining on the sediment surface were removed. The tray was inserted into the flume under conditions of very low flow (u_8 = 3 cm s^{-1}) and made flush with the adjoining flume bottom. For the cage treatments, the cage and its supports were secured to the tray at this time. All trials were conducted for 40 minutes except for u_* = 1.7 and 1.8 cm s^{-1} which ran for 10 minutes because these were part of another study.

For all runs, the sediment remaining in the sediment box after the experiment was sieved on a 500 μm sieve and the fraction retained was either sorted for clams immediately or preserved in 80% ethanol, stained with Rose Bengal, and sorted later. In order to ensure that we were not losing clams during sediment transfers, we conducted procedural controls using the medium size clams. Procedural controls followed the same procedure as the retention runs except that the tray was placed in the water table instead of the flume. These controls showed that an average of 99% of seeded

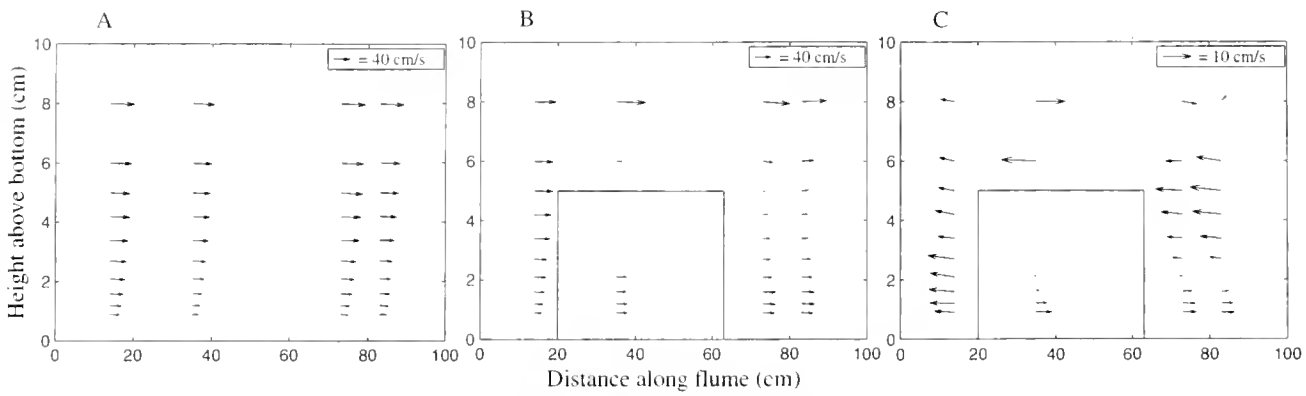

Figure 2. Vertical profiles of flow velocity (u) along flume with upstream shear velocity of $u_* = 1.8$ cm s^{-1}. A) Profiles without the cage (u); B) profiles with the cage (u_{cage}); C) deviations in velocity caused by the cage [i.e., $u_{cage} - u$]. clams were recovered, indicating that we were not losing clams while transferring the tray from the seawater table to the flume.

For retention trials, results were analyzed separately for each clam size, with cage (two levels, present and absent) and velocity as fixed factors in two-way analysis of variance (ANOVA) (Systat version 6.1). The dependent variable was the percentage of clams retained. For the medium size clam results, two separate two-way ANOVAs were performed due to different times of exposure to flow (10 and 40 minutes) and for large-sized clam results a one-way ANOVA for cage effect was performed. Visual inspection did not reveal any pronounced deviations from a normal distribution. Variances were tested and found to be homogeneous (Cochran's test; $p > 0.05$).

RESULTS

Cage Effects on Flow

A comparison of velocity profiles conducted with and without the cage indicates that the cage altered near-bed flow at both $u_* = 1.8$ cm s^{-1} (Fig. 2) and $u_* = 2.0$ cm s^{-1} (Fig. 3). Without the cage, velocities fit the expected log-linear profile, and changed little (<8%) with downstream distance (Figs. 2A, 3A). The presence of the cage disrupted this pattern by changing flows inside the cage, just above the upper rim of the cage's frame and just downstream of the trailing edge of the frame (Figs. 2B, 3B). Dye visualizations revealed that the leading face of the cage caused flow separation around the leading cross-sectional portion of the frame. The dye revealed eddies shedding off the upper edges of the cage and contributing to the observed increase in turbulence above and downstream of the cage. The velocity profiles indicated that mean velocities were reduced downstream of the cage at $u_* = 1.8$ cm s^{-1} and both within and downstream of the cage at $u_* = 2.0$ cm s^{-1} (Fig. 2C, 3C).

The effect inside the cage was different at $u_* = 1.8$ cm s^{-1} than at $u_* = 2.0$ cm s^{-1}. Flow deviations (Fig. 2C, 3C) indicated that velocities at $u_* = 1.8$ cm s^{-1} were increased inside the cage (at heights of 0.9, 1.2, 1.6 cm), yet at $u_* = 2.0$ cm s^{-1} these velocities were consistently reduced inside the cage. The vertical patterns of flow alteration were different at the two velocities. At $u_* = 1.8$ cm s^{-1} the flow deviations became less pronounced with height off of bottom, but at $u_* = 2.0$ cm s^{-1} the flow deviations became more pronounced with height off of bottom. These patterns suggest that the cage alters the flow most strongly at the sediment interface at $u_* = 1.8$ cm s^{-1} and at a height above the sediment interface at $u_* = 2.0$ cm s^{-1}.

The cage did have a small but measurable effect on water height in the flume. Upstream water heights along the flume increased in the presence of the cage, while downstream water heights decreased in comparison to no-cage heights at comparable target velocities. Water heights were elevated approximately 7% just in front of the cage (position C in Fig. 1) yet at the positions of our water height measurements and velocity profiles the increase was <3%. From the trailing edge of the cage to 3 m downstream, the heights were decreased by about 3% as compared to the no cage water heights. For the flow profiles at $u_* = 2.0$ cm s^{-1} and $u_* = 1.8$ cm s^{-1}, water heights over the cage were increased 4% and 2%, respectively. These water height deviations are relatively small and probably do not have a noticeable effect on flows within the cage. The proximity of the free-surface of the water to the upper face of the cage, however, may constrain the flow over the top of the cage.

Retention Trials

The cage tended to enhance retention of clams at some, but not all, combinations of clam size and shear velocity (Fig. 4). For small clams, slightly more clams were retained in cages, but the result was not statistically significant (Table 2). With medium size clams, there was no clear pattern of cage effect; neither treatment consistently retained more clams (Fig. 4). The only significant increase in clam retention with the cage ($p = 0.046$) occurred with the large clams at the greatest shear velocity used, $u_* = 2.0$ cm s^{-1} (Table 2). Potentially significant differences for the smallest category of clams could have been obscured by the high variability in results. On average, fewer than 8% of clams placed on the sediment box did not burrow.

Within a clam size, more clams tended to be eroded at higher velocities, but this trend was significant only for medium size clams for the comparison of $u_* = 1.7$ and 1.8 cm s^{-1} (Table 2). We had anticipated a direct relationship between shear velocity and clam erosion based on the study of Dunn et al. (1999). For our medium size clams, the relationship between velocity and clam

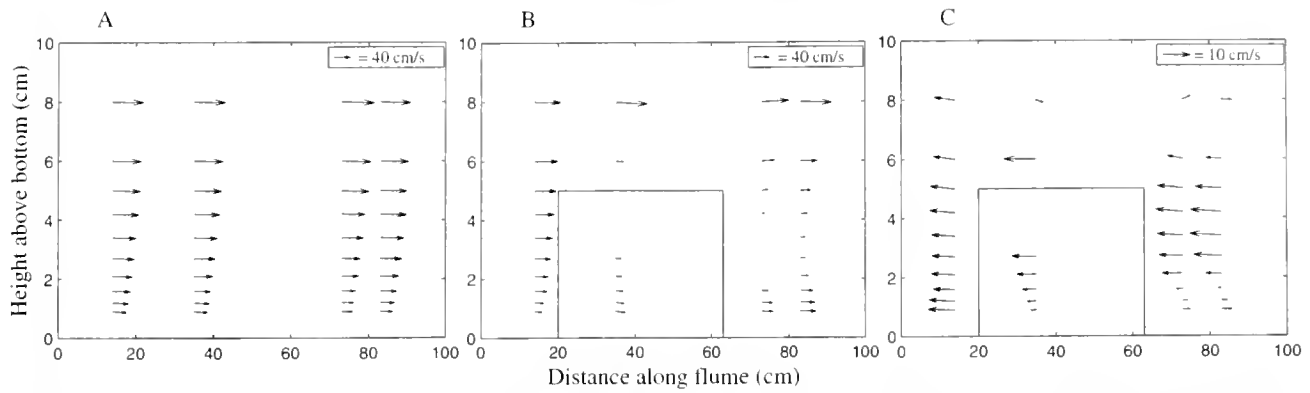

Figure 3. Vertical profiles of flow velocity (u) along flume with upstream shear velocity of $u_* = 2.0$ cm s^{-1}. A) Profiles without the cage (u); B) profiles with the cage (u_{cage}); C) deviations in velocity caused by the cage [i.e., $u_{cage} - u$]. Distances along the flume are relative and start 20 cm before the leading edge of the cage.

retention was not linear but appeared to have some critical velocity above which there was a notable reduction in clam retention.

DISCUSSION

Cage Effect on Clam Retention in the Flume

The most consistent result from our flume studies was the lack of a significant cage effect on clam retention in most flow regimes. This result was a surprise because the presence of a mesh structure along a flow path is known to alter flow patterns (Hulberg and Oliver 1980, Nowell and Jumars 1984), and natural mesh-like obstacles such as marsh grasses have been observed to reduce flow velocities by two to 10-fold (Gambi et al. 1990, Leonard and Luther 1995). A reduction in flow velocity was expected to occur in the cages and result in enhanced clam retention. The lack of significance did not appear to be due solely to low power of the statistical tests, as an increase in the number of replicate trials per treatment (from 3 to 4) did not result in higher significance (n = 4 for target shear velocities of $u_* = 0.7$ and 1.3 cm s^{-1}).

The one treatment that did show a significant effect of the cage on retention was the combination of the highest flow velocity ($u_* = 2.0$ cm s^{-1}) with the large clam size (SL = 2.3 mm). We

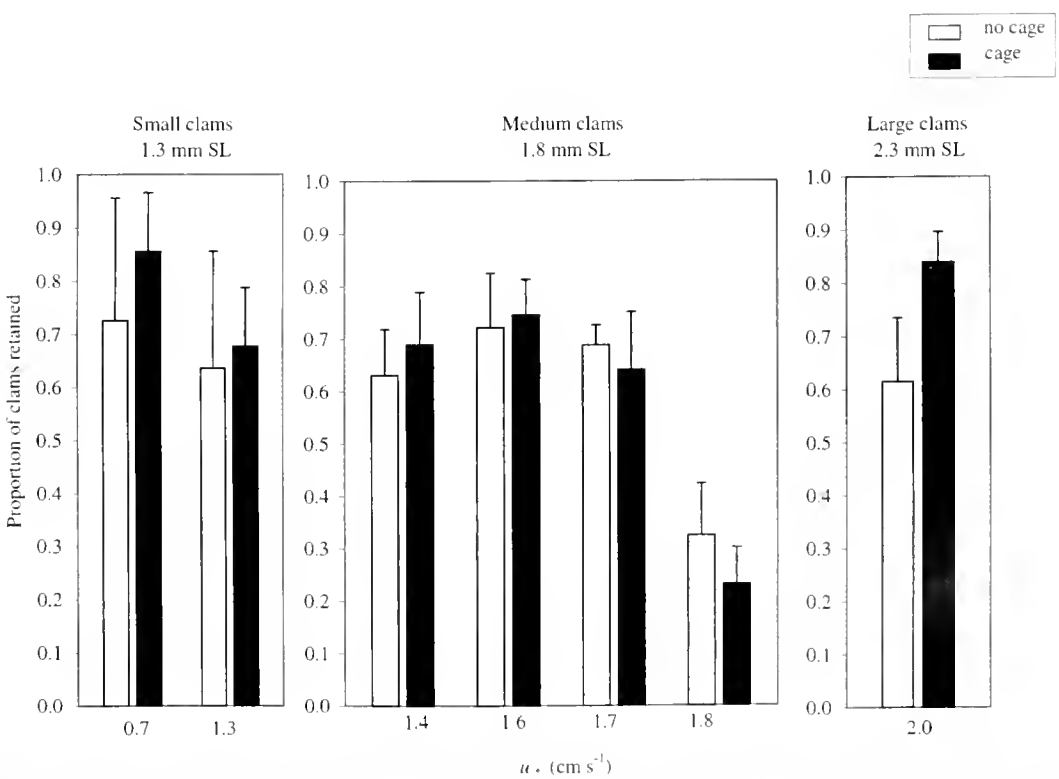

Figure 4. Mean proportion (±1 S.D.) of clams retained over a range of shear velocities with and without cage treatments. N = 3 for all runs except $u_* = 0.7$ and 1.3 cm s^{-1} where n = 4.

suggest that the mechanism for this cage effect is a substantial reduction in flow velocities within the cage in this particular flow regime. Reduced flow velocities should reduce the shear stress exerted on the sediment surface, thereby decreasing the rate of erosion of sediment and clams. This relationship between shear stress and erosion was observed in the present study for the medium size clam treatment at u_* = 1.7 and 1.8 cm s^{-1} (significant effect of velocity in Table 2), and has been reported by Roegner et al. (1995) and Dunn et al. (1999). We suspect that the absence of a significant cage effect on clam retention in flows slower than u_* = 2.0 cm s^{-1} was due to the failure of the cage to reduce boundary shear stress in these conditions.

Flow measurements recorded within the cage in the fastest oncoming flow treatment (u_* = 2.0 cm s^{-1}) and a slower flow (u_* = 1.8 cm s^{-1}) support our explanation for the clam retention results. The cage caused a measurable decrease in velocities near the sediment only in the fastest oncoming flow (Fig. 3). One plausible explanation for this effect is that the cage was starting to act more as a bluff body at the higher flows, blocking flow through the mesh and forcing the water up over the upper cage surface. This effect of producing a 'skimming flow' has been predicted and demonstrated for a sufficiently dense array of tubes or cylinders in boundary-layer flows (Morris 1955, Eckman et al. 1981, Nowell and Jumars 1984). We speculate that a comparable process occurs in our cage at oncoming flows of u_* = 2.0 cm s^{-1} and higher: in this flow regime, the velocities are high enough to produce turbulent wakes downstream of the mesh filaments, increasing their effective diameter and decreasing the fluid 'porosity' of the cage (Taylor 1948, Gerrard 1978).

An alternative explanation for the observed significant cage effect in the u_* = 2.0 cm s^{-1} treatment is that suspension of the larger-sized clams was more sensitive than that of the smaller ones to flow alterations caused by the cage. We do not think this is a valid explanation for several reasons. Firstly, there is no evidence for an increasing sensitivity of clam suspension to caging with increased clam size; instead, the small and large clams tended to have increased retention under the cage, whereas the medium size clams showed a mixed response. Secondly, because larger clams are capable of burrowing deeper than small ones, one would expect them to be less, and not more, sensitive to caging effects. Finally, we have no independent evidence for the "clam size" hypothesis, whereas we do have independent flow measurements in the cage that support the "flow threshold" hypotheses. For these reasons, we constrain our discussion to the latter.

Behavioral Effects on Clam Retention

A reduction in near-bottom flow velocity may enhance clam retention through both hydrodynamic and behavioral mechanisms. A critical shear stress is necessary to suspend clams of any particular size; reducing the shear stress below this level will result in more limited transport. Reducing the shear stress will also reduce the rate of sediment erosion, potentially allowing clams more time to burrow below the unstable sediment layer. Either or both of these processes are likely responsible for the relationship between higher shear stresses and enhanced clam transport reported in flume (Roegner et al. 1995, Dunn et al. 1999) and field (Emerson and Grant 1991) studies.

Although surficial sediment was eroded under the cage in our trials at u_* = 2.0 cm s^{-1}, the reduction in rate of erosion relative to uncaged flows may have allowed clams to remain buried in the sediment. In order to maintain access to the sediment-water interface, postlarval *M. arenaria* of 1.3 to 2.3 mm SL can only burrow as deep as their siphons are long, usually to depths of 7.5 mm or less (Zwarts and Wanink 1989). We speculate that *M. arenaria* may actively burrow to avoid being exposed and eroded as Sakurai and Seto (1998) demonstrated for the surf clam, *Pseudocardium sachalinensis* at the reduced shear velocities but not at ambient uncaged shear velocities. Thus we suggest that the reduction in shear stress offered by the cage at u_* = 2.0 cm s^{-1} sufficiently reduced the erosion rate so that 2.3 mm clams could maintain their position in the sediment and avoid resuspension.

Based on the siphon length-burial limitation, we expected to find that for any specific shear velocity, retention of larger clams would be greater than retention of the smaller clams. Although our data alone do not strongly support this hypothesis, comparison with another study demonstrates a retention-size relationship. We found that 25–35% of our 1.8 mm clams were retained at u_* = 1.8

TABLE 2.

Summary of ANOVAs examining the effects of cage and velocity on retention over a range of size categories.

Clam Size	Source	Sum-of-Squares	df	Mean-Square	F-ratio	P
Small	Cage	0.030	1	0.030	0.939	0.352
	Velocity	0.072	1	0.072	2.289	0.156
	Cage*Velocity	0.008	1	0.008	0.243	0.631
	Error	0.378	12	0.031		
Medium	Cage	0.005	1	0.005	0.609	0.457
	Velocity	0.016	1	0.016	1.912	0.204
	Cage*Velocity	0.001	1	0.001	0.104	0.755
	Error	0.066	8	0.008		
Medium*	Cage	0.015	1	0.015	2.099	0.185
	Velocity	0.448	1	0.448	64.70	<0.001
	Cage*Velocity	0.002	1	0.002	0.232	0.643
	Error	0.055	8	0.007		
Large	Cage	0.076	1	0.076	8.129	0.046
	Error	0.037	4	0.009		

* Separate ANOVAs were performed on two sets of mid-season clams because those tested at u_* = 1.7 and 1.8 cm s^{-1} were exposed to flow for only 10 min (Systat version 6.1).

cm s^{-1}, yet Roegner et al. (1995) reported that 0% of their 0.24–0.29 mm clams were retained at a comparable velocity ($u_* = 1.75$ cm s^{-1}). Thus smaller clams were more readily transported at this particular velocity and retention appeared to correlate with clam size.

Relevance to Field Applications

Our flume results suggest that mesh cages used in the field may enhance retention of recently settled bivalves in flow velocities above a critical level. The extent to which our flume experiments are applicable to field environments depends on how well they represent field situations hydrodynamically, biologically, and structurally. The shear stresses used in the flume experiments fall within those measured at Barnstable Harbor (authors' unpublished data), indicating that boundary-layer flows in the flume are a reasonable representation of field flows. The cultured clams burrowed actively, and their sizes covered the range observed in field populations during first season growth. The cage used in the flume had the same mesh size and composition (flexible mesh), but a much smaller overall size, as mesh enclosures used in the field. Thus, we expect our qualitative prediction (mesh enclosures enhance bivalve retention only above a threshold shear stress) to be broadly applicable, but the specific threshold level to depend somewhat on the geometry and mesh size of the cage.

A reduction in resuspension caused by caging will notably influence population density only if loss via resuspension is a significant source of total loss. Other processes influencing loss include mortality through predation, disease, and/or inadequate resources. Manipulative field experiments evaluating the relative influences of hydrodynamic resuspension and predation on *M. arenaria* recruits indicate that resuspension is a significant cause of loss, especially in smaller size-classes (authors' unpublished data). Therefore, we expect that the possible increase in retention caused by caging could have a significant impact on population density by the end of the first season.

Our flow and retention results are consistent with experimental field evidence suggesting that clam recruitment under cages could be enhanced at high flows. Marcotti and Leavitt (1997) tested the hypothesis that cages, in the form of suspended tents of plastic mesh (mesh size = 0.5 cm), would increase clam recruitment in field manipulations at Barnstable Harbor, Massachusetts. They found that the only site at which the cages significantly enhanced recruitment (Green Point) was one of the two sites with the highest tidal flow rates. Velocity records from the Green Point site indicated that over a 10 h period during a spring tide, 40% of the flow velocities corresponded to $u_* = 2.0$ cm s^{-1} or greater (authors' unpublished data). Thus velocities at Green Point commonly were high enough to produce the caging effect demonstrated in our flume experiments, suggesting that the enhanced recruitment may have been due to cage-induced retention.

Because mesh enclosures are more likely to retain clam juveniles in vigorous rather than quiescent flow environments, the hydrodynamic setting of a site is an important factor to be considered in their use. This consideration should be included with others, such as the potential of the enclosures to enhance initial settlement, enhance or deplete food resources or reduce mortality through predator exclusion, when predicting whether they are likely to increase population densities. Mesh enclosures are currently in use in multiple embayments along the New England coast and the results of these applications will help refine the cost-benefit analysis of their use and identify the habitats where they will substantially increase the numbers of harvestable soft-shell clams.

ACKNOWLEDGMENTS

We thank Rob Dunn, Anna Metaxas, and Susan Mills for their assistance with the flume experiments. We thank Stace Beaulieu for helpful suggestions on the manuscript and assistance with the flume work. The authors also thank Rob Jennings and an anonymous reviewer for improving the manuscript. Beals Island Shellfish Hatchery and Mook Sea Farm provided clams and advice. GROWTH OF BUTTER CLAMS, *SAXIDOMUS GIGANTEUS* DESHAYES, ON SELECTED BEACHES IN THE STATE OF WASHINGTON

STUART ALAN GOONG AND KENNETH K. CHEW
University of Washington School of Aquatic and Fishery Sciences, Box 355020, Seattle, Washington 98195

ABSTRACT The butter clam, *Saxidomus giganteus* Deshayes, is a highly valued recreational shellfish species, but is currently of little commercial importance in Washington. Recently, a small-scale commercial butter clam harvest began, and interest in this species is expected to increase. Basic information on the biology and ecology of the clam is necessary to establish a sound management regime for recreational and potential commercial harvest of butter clams. Beaches studied were Birch Bay State Park, Double Bluffs, and Potlatch State Park. Growth rates were determined by measuring lengths-at-age for clams collected from each beach. Von Bertalanffy growth curves were produced using nonlinear regression analysis. Growth rates were significantly different among the three beaches, with the fastest growth occurring at Double Bluffs, followed by Birch Bay State Park, while clams at Potlatch State Park had the slowest growth.

KEY WORDS: *Saxidomus giganteus*, growth

INTRODUCTION

The purpose of this investigation was to assess whether growth of butter clams (*Saxidomus giganteus* Deshayes) on selected beaches in Washington differed. Beaches selected for this study were Birch Bay State Park, Double Bluffs, an Island County recreational area on the southwestern coast of Whidbey Island, Washington, and Potlatch State Park (Fig. 1). There was no evidence to suggest that growth rates might differ within the Puget Sound Basin, although different growth rates have been observed for butter clams from beaches within close proximity in British Columbia (Quayle and Bourne 1972).

The three beaches included in this study were surveyed for butter clams using methods similar to beach survey methods used by the Washington Department of Fish and Wildlife (WDFW). Clam shells were aged using the annular method, which appears to be the most reliable method of age determination for butter clams (Goong 1999). At least two researchers have independently verified deposition of annuli in the shell of the butter clam using mark and recapture studies in Washington and British Columbia (Houghton 1973, Neil Bourne pers. comm.). Growth rates were calculated using von Bertalanffy methodology (von Bertalanffy 1938).

MATERIALS AND METHODS

Study Areas and Habitat

Two hundred and forty-one butter clams were collected from three beaches for this study from August 17–19, 1997. Clams were collected from Birch Bay State Park on August 17, from Double Bluffs on August 18, and from Potlatch State Park on August 19.

Birch Bay State Park is located near Bellingham at the southern end of the Strait of Georgia. The beach has a gradual slope, and is characterized as primarily a sand-rock beach, with numerous larger cobblestones (up to 15 cm × 15 cm) on the surface. The beach has good road access, with parking less than 50 m from the water. This allows heavy recreational use, including clam harvesting, judging from the large number of clam harvesters observed and poor clam densities found on the beach. Other clam species observed on the beach included many Manila clams (*Tapes philippinarum*) and a few native littleneck clams (*Protothaca staminea*). Green shore crabs (*Hemigrapsus* sp.) were common. Water quality measurements, as recorded by the Washington Department of Ecology (WDOE) (Newton et al. 1997), showed surface temperatures averaged 7°C in winter and 10–13°C in summer. Salinity was fairly constant, ranging from 24–27 ppt throughout the year. The concentration of chlorophyll *a* was about 0.6 μg/L in winter, and about 3 μg/L during the rest of the year.

Double Bluffs Beach is located on the southwestern coast of Whidbey Island, in central Puget Sound. Substrate and topography of this beach was similar to that of Birch Bay. There was poor road access, with a parking area located approximately 1 km from the southern boundary of the clam bed. This beach probably has little recreational harvest, judging from the few clam harvesters observed, high clam densities, and large numbers of older clams found there. Other species of clams observed on this beach included small numbers of Manila clams, cockles (*Clinocardium nuttalli*), bent nose clams (*Macoma nasuta*), and horse clams (*Tresus capax*). There were also large numbers of green shore crabs and acorn barnacles (*Balanus* sp.). One juvenile cancrid crab was also observed. Sea surface temperatures averaged 8°C in winter and 10–12°C in summer, a temperature regime similar to that of Birch Bay. Salinity averaged 29 ppt throughout the year. Chlorophyll *a* concentrations were about 0.4 μg/L in winter, and about 4.3 μg/L in summer. These water quality measurements were similar to those found at the WDOE sampling station near Birch Bay. Lower salinity measurements for the station near Birch Bay may be due to the influence of freshwater from the Fraser River in southern British Columbia (Newton et al. 1997).

Potlatch State Park is at the southern end of Hood Canal near the southern end of the Puget Sound Basin. The topography of this beach was more complex than the other two beaches. Much of the beach was flat near the road, then sloped gradually upward toward the water, and then downward. However, some portions of the beach sloped gradually downward the entire distance to the water. Because of this, much of the flat area of the beach is flooded during high tide and had good clam populations, despite being fairly distant (50 m or more) from the water level during minus tides. Substrate of this beach was best characterized as mud-gravel, and there were no cobblestones on the surface. Sampling of this beach coincided with the final day of a three-day native tribal Manila clam harvest, during which butter clams were also collected. Thus, clam densities were poor, and most clams collected

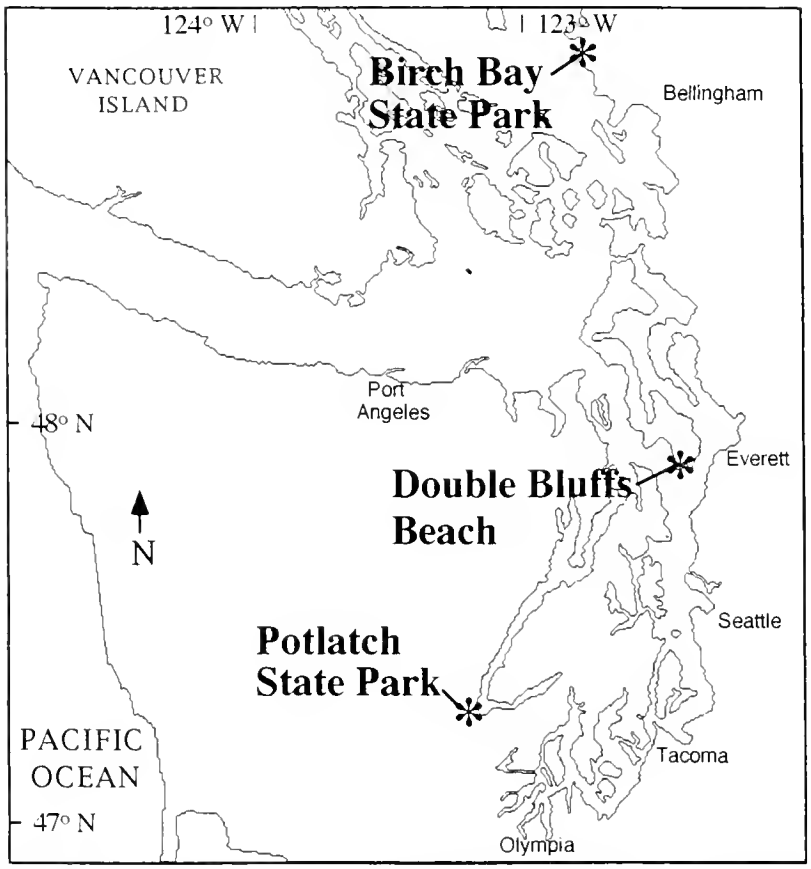

Figure 1. Map of the Greater Puget Sound Region showing locations of the three study sites.

were in the 3+ age class or younger. Other clam species observed on this beach included a few bent nose clams and numerous Manila clams. Surface temperatures averaged 7°C in winter and 14–18°C in summer. Salinity was highly variable, due to freshwater drainage from the Skokomish River and several small creek systems, but ranged from 16–26 ppt. Chlorophyll *a* concentrations were also highly variable, but tended to be quite low during summer months, averaging only about 0.9 μg/L. The two other beaches had steady concentrations of chlorophyll *a* from spring through autumn, with low chlorophyll *a* concentrations only in winter months.

Sampling Methods

Sampling was undertaken using survey methods similar to those employed by WDFW (Campbell 1996). A reference transect was established on each beach which ran perpendicular to the shoreline. The end of the transect nearest the high water line was situated approximately 30.5 m from the water line at the low tide mark. A 30.5 m length of rope was laid along the transect down to the water line. The rope was marked with a permanent marker every 1.5 m so it could be used to measure distances on the beach. Quadrats of 0.25 m^2 in area were established every 4.5–10.5 m along the length of the transect to ensure that clams were collected from different tidal heights. Positions of the quadrats occasionally had to be adjusted in order to account for beach topography. Subsequent transects were established 9–15 m from each other and the reference transect, and were also perpendicular to the shoreline. Quadrats were established along these transects in a similar manner and excavated to a depth of 0.5 m.

Quadrats were excavated using standard garden spades. As quadrats were excavated, rocks and other large debris were removed. Large butter clams were removed and collected. The remainder of the substrate was sifted through 1-cm mesh screens in order to collect smaller clams.

Analysis of Growth

Data were analyzed using the von Bertalanffy growth model (von Bertalanffy 1938):

$$l(t) = L_\infty - L_\infty e^{-k(t - t_0)},$$

- $l(t)$: length at age t
- e: base of the natural logarithm
- t_0: time when length is theoretically zero
- k: von Bertalanffy growth constant
- L_∞: asymptotic maximum length of the clam.

Model parameters were estimated using nonlinear regression analysis, as suggested by Gallucci and Quinn (1979), in lieu of the Ford-Walford method. Gallucci and Quinn (1979) noted that use of nonlinear regression facilitates quantitative comparisons among the parameters of the equation. Commonly, comparisons are made on the growth constant (k) only. Since it is standard practice to report differences in k as representing differences in growth, this convention was followed in the present study. An F test was utilized in order to make statistical comparisons among parameters

(Neter et al. 1996). Statistical analyses were performed with SPSS 6.1.1S for the Power Macintosh.

RESULTS

Von Bertalanffy Growth Analysis

Von Bertalanffy growth models resulting from these parameters are plotted in Figure 2. Portions of these curves corresponding to the first 9.5 years of growth are redrawn in Figure 3 to exhibit greater detail.

Figure 3 clearly shows that growth is different among beaches. Fastest growth occurred at Double Bluffs, followed by Birch Bay, while slowest growth was observed at Potlatch. However, although the rate of growth was slower at Potlatch, it did not appear to decrease over time as quickly as it did at the other beaches. This is probably due to an inadequate number of older specimens in the sample from Potlatch. Most clams collected from Potlatch were in the 3.5-year age class or younger. The result is a paucity of growth data beyond the first four years, possibly leading to a poorly fitting growth model. One indicator of this possibility is the L_∞ calculated for Potlatch shown in Table 1. This is an unreasonably large value for maximum clam length. However, the early part of the curve fits the data. Thus, the model may still adequately describe growth for the first several years.

The growth constants (k) listed in Table 1 support conclusions drawn from Figure 3. Fastest growth occurred at Double Bluffs, while slowest growth occurred at Potlatch. Differences among the three beaches were significant at the $\alpha = 0.05$ level.

DISCUSSION

Differenees Among the Three Beaches

Of the three beaches, Potlatch is the most diverse. Potlatch is a mud-gravel beach, which is somewhat different from the preferred butter clam substrate of sand, shell, and gravel (Quayle and Bourne 1972). The substrate at Potlatch is more suited to Manila clams (*T. philippinarum*), as evidenced by the numbers of Manila clams observed on this beach. Double Bluffs, where the fastest growth occurred, and Birch Bay are both sand-rock or sand-rock-shell beaches. In addition, butter clams were most abundant at Double Bluffs.

Potlatch is more influenced by freshwater drainage than the other two beaches. Results of the present study indicate that butter

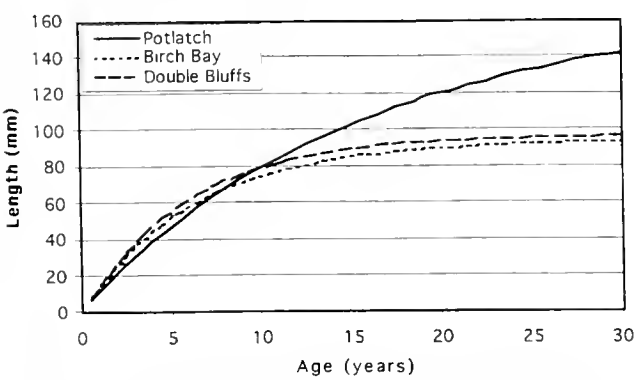

Figure 2. Von Bertalanffy growth curves for butter clams from Potlatch State Park, Birch Bay State Park, and Double Bluffs Beach, Washington.

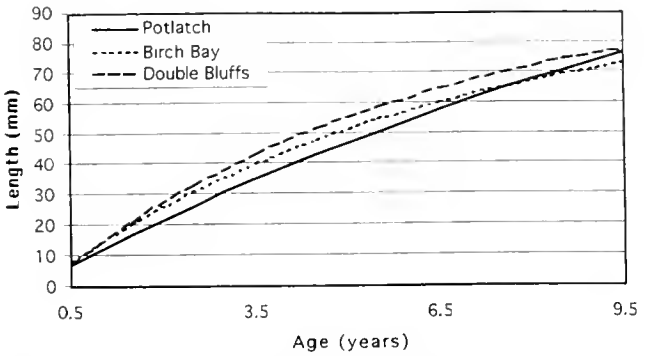

Figure 3. Von Bertalanffy curves for butter clams from Potlatch State Park, Birch Bay State Park, and Double Bluffs Beach, Washington, plotted to 9.5 years.

clam growth may be positively correlated with salinity. Although no other butter clam studies support this suggestion, studies on oysters suggest that oyster growth may be influenced by differences in salinity (Toro et al. 1995, Mallonee 1989). Robert et al. (1993) conducted a study of Manila clam growth at three sites, one of which was oceanic and the others were estuarine. Clam growth was fastest at the oceanic station, and they speculated that differences in growth were due in part to differences in salinity. Like butter clams, Manila clams are venerid clams. Bardach et al. (1972) reported that the optimum salinity range for Manila clams was about 24–32 ppt, which is the normal salinity range for Puget Sound. This salinity range may also be optimal for butter clams. Average salinities recorded at Potlatch are normally below this range, ranging from 16–26 ppt (Newton et al. 1997).

As noted in Study Areas and Habitat, surface water temperatures at Potlatch tended to have greater fluctuations than temperatures at the other beaches. This may be important if butter clams are better adapted to more stable growing areas. Further, water temperatures in summer at Potlatch can be particularly high relative to those at the other beaches. Irregularity in year round water temperatures and excessive summer temperatures could cause a sufficient amount of stress to have a negative impact on growth. Temperature has been shown to be an important determinant of bivalve growth in several species, including another venerid clam, the northern quahog (*Mercenaria mercenaria*), scallops, and oysters (Crockett 1988, Claereboudt 1994, Toro et al. 1995). Mann and Glomb (1978) and Mann (1979) showed a negative correlation between temperature and growth in Manila clams, with fastest growth occurring at 12°C. Growth was also correlated with water

TABLE 1.

Parameters of the von Bertalanffy growth equation for butter clams from three beaches in Washington, calculated using all annulus lengths.

Beach	k ± SE	L_∞ ± SE	t_0 + SE
Potlatch State Park	0.064 ± 0.010	165.903 ± 20.243	−0.222 ± 0.048
Birch Bay State Park	0.157 ± 0.010	93.870 ± 3.218	−0.083 ± 0.051
Double Bluffs Beach	0.172 ± 0.006	96.905 ± 1.542	0.043 ± 0.032
Total	0.140 ± 0.004	105.157 ± 1.892	−0.004 ± 0.026

temperature in Bourne (1982), but the correlation was positive. Fastest growth in natural populations of Manila clams occurred in the Strait of Georgia, where surface water temperatures are highest, commonly above 15°C in summer (Hollister and Sandes 1972). However, Mann's results were from laboratory experiments, and some other factor may be responsible for the observed differences in growth in British Columbia.

In addition, food availability was more irregular at Potlatch, as indicated by chlorophyll *a* concentrations. There appears to be higher food availability during spring and autumn. Winters at Potlatch are times of low food availability. Unlike the other beaches, there was also low food availability at Potlatch during summer. At Double Bluffs and Birch Bay, food availability was consistent from spring through autumn. This is supported by the dissolved inorganic nitrogen levels at Potlatch, which are frequently undetectable from May through August in the surface water (Newton et al. 1997). Dissolved inorganic nitrogen is generally considered the limiting nutrient in marine ecosystems (Valiela 1984). Thus, maximum primary productivity at Potlatch may be a growth limitation for bivalves at Potlatch. Food availability has been shown to be among the most important determinants of bivalve growth, including growth in *M. mercenaria* (Claereboudt 1994, Mallonee 1989, Crockett 1988). Foe and Knight (1985) found that Asiatic clams (*Corbicula fluminea*) are probably food limited in the Sacramento-San Joaquin Delta, even with chlorophyll *a* concentrations as high as 62.5 µg/L, which is an order of magnitude higher than concentrations found in Puget Sound.

Finally, there is also a gradient of human activity at these three beaches. Potlatch may be a site of intense harvesting, if not for great numbers of butter clams, then certainly for Manila clams. Also as noted earlier, there was a commercial harvest by Native American harvesters. Birch Bay is not subject to commercial harvest, but is heavily used for recreational purposes, since the roadway allows direct road access to the beach. Double Bluffs is also not available to commercial harvesting and probably has little recreational use of the butter clam resource due to distance of the clam bed from the road access. One effect of heavy use may be substrate compaction. Studies conducted in Washington demonstrated that substrate compaction may be an important cause of low productivity on clam beaches (Toba et al. 1992). Increased human activity in an area has been shown to decrease biological integrity, resulting in decreased species diversity, and may have negative impacts on growth and health in general on all taxa in a given ecosystem (Karr 1981). Houghton (1973) showed a high correlation between taxa richness and growing areas with high clam densities, strong growth, and high productivity. Thus, bivalve growth may be negatively correlated with a gradient of human activity. Indeed, this may be an important factor in growth on popular recreational clam beaches, although it is probably negligible on more remote beaches, such as Double Bluffs.

Patchiness in age distribution may have affected growth analysis for Potlatch State Park. In the von Bertalanffy analysis for Potlatch, the lack of strong representation of older clams likely contributed to the computation of an unrealistic L_∞, causing the Potlatch curve to eventually cross the others. If the true asymptote for Potlatch is closer to those of the other beaches as is suspected, the curve would probably not cross the others. It should be noted that the calculated parameters are still adequate to describe the observed growth for at least the first four years. Due to poor data for subsequent years, the model does not provide an adequate description of growth for later years.

CONCLUSIONS

1. Butter clams from different beaches in Puget Sound, Washington have different rates of growth. Fastest growth occurred at Double Bluffs, and slowest growth occurred at Potlatch.
2. The legal size limit for butter clams in Washington probably should be increased. The current size limit for butter clams is 38 mm. According to results of growth analysis, clams in this size class would be only about 2–3 years old. It is suggested that the size limit be increased to about 63 mm, the size limit in British Columbia. Clams in this size class would be about six years old, and would have had opportunities to spawn.
3. Since rates of growth are different in different growing areas, it is suggested that a more localized management approach for the resource be utilized in order to protect the productivity of the stock. A generalized management strategy will not optimally manage the resource. This would require growth analyses to be performed in any area that has any commercial or intense recreational harvests for butter clams.

ACKNOWLEDGMENTS

The senior author wishes to express his appreciation to his Supervisory Committee for their invaluable guidance, Drs. Kenneth Chew, Neil Bourne, and Loveday Conquest. Thanks also to my field crews for all of their hard work. Finally, special thanks to the Graduate School of the University of Washington, the Loosanoff Foundation, and the Research, Admissions, and Scholarship Committee of the School of Fisheries at the University of Washington for their generous financial support.

REGENERATION OF THE INHALANT SIPHON OF *DONAX HANLEYANUS* (PHILIPPI, 1847) (BIVALVIA, DONACIDAE) FROM ARGENTINA

DIEGO C. LUZZATTO[1] AND PABLO E. PENCHASZADEH[2]

[1]*Lab. Invertebrados, Depto. Biología, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Ciudad Universitaria, Pab II, C1428EHA, Buenos Aires, Argentina;* [2]*Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, MACN-CONICET, Av. Gallardo 470, 1405 Buenos Aires, Argentina*

ABSTRACT *Donax hanleyanus* (Philippi, 1847) is the southernmost *Donax* species in the American Atlantic. It inhabits intertidal fine grain sandy shores in northern Buenos Aires Province. As with other species in this genus, these animals survive under pressure of "cropping" by fish that feed on their siphons. The inhalant siphon is a complex organ; its tip contains a system of branched tentacles that permit particle selection of medium and large grains and prevent their entry to the pallial cavity of the animal. To estimate the regeneration speed of the amputated siphon under laboratory conditions, a study of the regrowth sequence after an artificial cut was performed at regular intervals for complete 10-day periods. The observations *in vivo* under the microscope were correlated with those made by histology at the same time intervals. Results indicate that at 24 h after amputation, rudiments of the primary tentacles are observed, and the siphon is fully active in selecting particles at the fifth day (i.e., the process of regeneration of the primary, secondary, and tertiary tentacles is completed within ~5 days). After this, a period of growing and tentacle ramification follows, even though the result is a siphon with tentacles less ramified than the original.

KEY WORDS: bivalve, inhalant siphon, siphonal regeneration, *Donax hanleyanus*

INTRODUCTION

Beach clams of the Tellinacean genus Donax inhabit intertidal sandy beaches in most parts of the world. *Donax hanleyanus* (Philippi, 1847) is the only Donax species occurring throughout the Argentine littoral. These bivalves are constantly flushed out of the sand by the pounding surf; they are adapted to live on exposed shores, and they do not occur on protected beaches or in shallow bays. *D. hanleyanus* require an environment in which there is a fair amount of wave action to keep the sand aerated and clean, to keep organic detritus in suspension, and to allow tidal migration (Ansell 1983, Ansell & Trevallion 1969, Mori 1938, Mori 1950, Narchi 1978, Penchaszadeh & Olivier 1975).

The siphons of *D. hanleyanus* are very flexible and extensible, as are those of other tellinacean bivalves. When buried, *D. hanleyanus* extends its inhalant siphon through the sediment into the water above (~1.5 cm for a 2-cm animal). Juvenile flatfish (Trevallion 1971, Gillbert & Suchow 1977, de Vlas 1979), crabs (Hughes 1969), and birds (Ansell 1981) feed on tellinacean siphons. Some studies have included an examination of the process of wound healing or the physiological basis of the regeneration, focusing on the amount of regenerated tissue (Hodgson 1982a, Hodgson 1982b, Peterson & Quammen 1982).

Siphon regeneration after amputation has been described for the tellinaceans *Tellina tenuis* da Costa (Trevallion 1971), *Scrobicularia plana* (da Costa), *D. serra* Röding (Hodgson 1982a, Hodgson 1982b), and *D. vittatus* (Ansell et al. 1999).

The external surface of the tip of the inhalant siphon of *D. hanleyanus* has six branched primary tentacles, six branched secondary tentacles between two primary tentacles, twelve small tertiary tentacles between a primary and a secondary tentacle, and 24 smaller quaternary tentacles between two tertiary tentacles (Fig. 1), which are very mobile. These tentacles form an intricate sieving device (Narchi 1978).

The siphons of *D. hanleyanus* are very sensitive to vibrations. They are richly innervated and rich in sense organs, at least near the tips (Hodgson 1982b, Ansell et al. 1999). It would be beneficial to the animal if damaged or lost parts of the siphons could regenerate rapidly after injury so as to regain normal function.

The aim of this study was to examine how soon the normal tip of the inhalant siphon of *D. hanleyanus* is regenerated, focusing on the proper function of filtration, and to study the morphological characteristics of the siphon regeneration by simulating the effect of a cropping predator.

MATERIALS AND METHODS

The animals were collected from sandy beaches in Punta Mogotes (Mar del Plata), at low tide. We selected specimens that were approximately 2 cm in shell length. Previously in the lab, aquaria had been conditioned with $CaCO_3$-saturated seawater at 35‰ salinity and pH 7.8. The experimental aquarium device consisted of two fishbowls, one of 200 l and the other of 10 l. The small one was inside the big one. Sand extracted from the sampling areas was placed inside the small one. Water was pumped from the big one

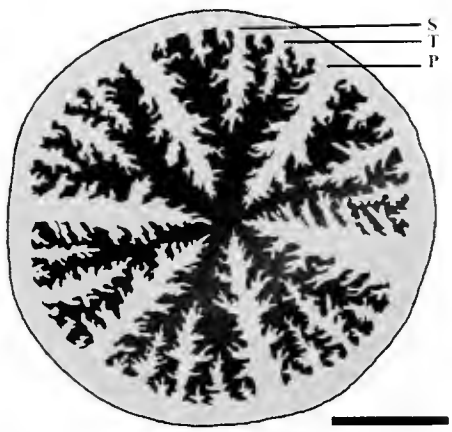

Figure 1. View of the inhalant siphon tip of *Donax hanleyanus* showing tentacles and ramifications. P: primary tentacles; S: secondary tentacles; T: tertiary tentacles. Scale bar: 0.5 mm. (After Wade, 1969)

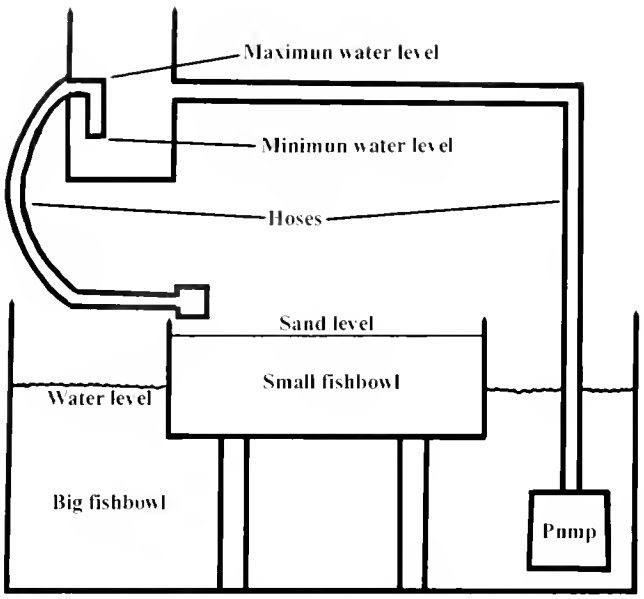

Figure 2. Aquaria device scheme to recreate the high-energy conditions of the natural environment of *Donax hanleyanus*.

to a third bowl located 1 m above. Water from this third bowl siphoned its contents into the small fishbowl and in this way it kept the sand and water aerated and turbulent, simulating the high-energy conditions of the natural environment of these animals (Fig. 2). The animals were exposed for at least 10 days to this aquarium system, and the temperature was kept between 20 and 22°C during the experiments.

After the adaptation period, 30 *D. hanleyanus* were placed in a shallow glass dish containing sea water and left undisturbed until the siphons were extended. The tip of the inhalant siphon was removed from un-narcotized individuals using ophthalmic scissors (1 to 2 mm from the tentacle crown). Five siphons, used as controls of the initial regeneration point, were fixed immediately in Bouin solution for 24 h. The remaining 25 animals were left to recover in the running sea water system described above, which contained a layer of sand deep enough to allow the animals to burrow normally. These animals were sacrificed in groups of five at 1, 3, 5, 7, and 10 days, always extracting the siphon tip and fixing it in Bouin solution. All of these fixed siphon tips were processed histologically. A dehydration and paraffin inclusion protocol was followed, and transverse sections were cut at 7 microns, after which hematoxylin-eosin tint was used.

Because it is difficult to obtain histological cuts of the siphon tip always in the correct orientation, we chose the best ones for analysis and photography.

The changes that followed the initial cut on the living animals were observed daily under a stereoscopic microscope to give *in vivo* corroboration.

Drawings were made from observations under the stereoscopic microscope for living animals and the histology microscope for fixed siphons. Each drawing is a composit of all the information of a specific regeneration point. The qualitative regeneration curve resulted from digital images of these drawings at 600 dpi in black and white (siphon black and background white). Using a computer, we counted the number of pixels in black to calculate a percentage index of coverage as (number of black pixels)/(number of total pixels) × 100. This index was graphed against time in days.

This protocol was repeated twice to provide experimental corroboration.

All the experiments were made with the animals in starving conditions, and a control group of undisturbed non-excised animals was used to test viability during the experiments.

RESULTS

For the histological interpretation of the complex tentacle system of the inhalant siphon of *D. hanleyanus*, we classified the different tentacles according to the shape and quantity of the branches. This primary filtration organ comprises 6 branched primary tentacles, 6 branched secondary tentacles between the primary tentacles, and 12 tertiary tentacles between a primary and a secondary tentacle. Every tentacle thinner than a tertiary tentacle was considered as a branch.

The observations made under stereoscopic microscope revealed that the tentacles not only form a net that selects the grain size but also that the tentacles have the capacity to change the diameter of the siphon opening. This is shown in Figure 3, which illustrates how the siphon acts to occlude the opening and prevent the entry of large particles of sand. The structure of each tentacle and of the whole siphon, comprised of longitudinal and circular muscles, enables it to contract and elongate (Fig. 4).

The regeneration sequence of the inhalant siphon is shown in Figures 5 and 6. The first rudiment of the new six primary tentacles is visible 24 h after the cut, and they are developed in 48 h. After the third day the secondary tentacles appear, and after the fifth day they are well differentiated from each other. On the seventh day all tentacles (i.e., primary, secondary, and tertiary) are very well developed, and at this time we can affirm that the siphon is totally functional. In the later stages its branches began to be observed in the tentacles, but from this time the regeneration rate diminishes

notably. Moreover, after 10 days the complexity and ramification quantity is still not the same as the control siphon (Fig. 5).

An approximation of the regeneration rate is shown in Figure 6, where the degree of regeneration point corresponds to standardized drawings. In the figure a lag period in the regeneration can be observed during the first 24 h. This is followed by a period of very intensive regeneration between the second and fifth day, and finally the process is decelerated until the end of the regeneration.

The animals used as controls (undisturbed animals) remained alive after 40 days, and no mortality was detected during the experiments in the excised animals. We did not record any difference on the siphon-restoring rate during the second experiment series.

DISCUSSION

The morphology and internal anatomy of the siphons of Tellinacea have been well described (Yonge 1949), although in *Donax* there are generally more tentacles than Yonge supposed, and in life most extend across the siphonal aperture forming a protective screen that excludes sand particles rather than all being turned back, as Yonge described. The siphons of *D. hanleyanus* do not differ significantly from those of the closely related European species *D. trunculus* L. (Moueza & Frenkiel 1974) and *D. vittatus* (Ansell et al. 1999). The siphons of these three species are closely similar in many respects to other Donax species (Duval 1962,

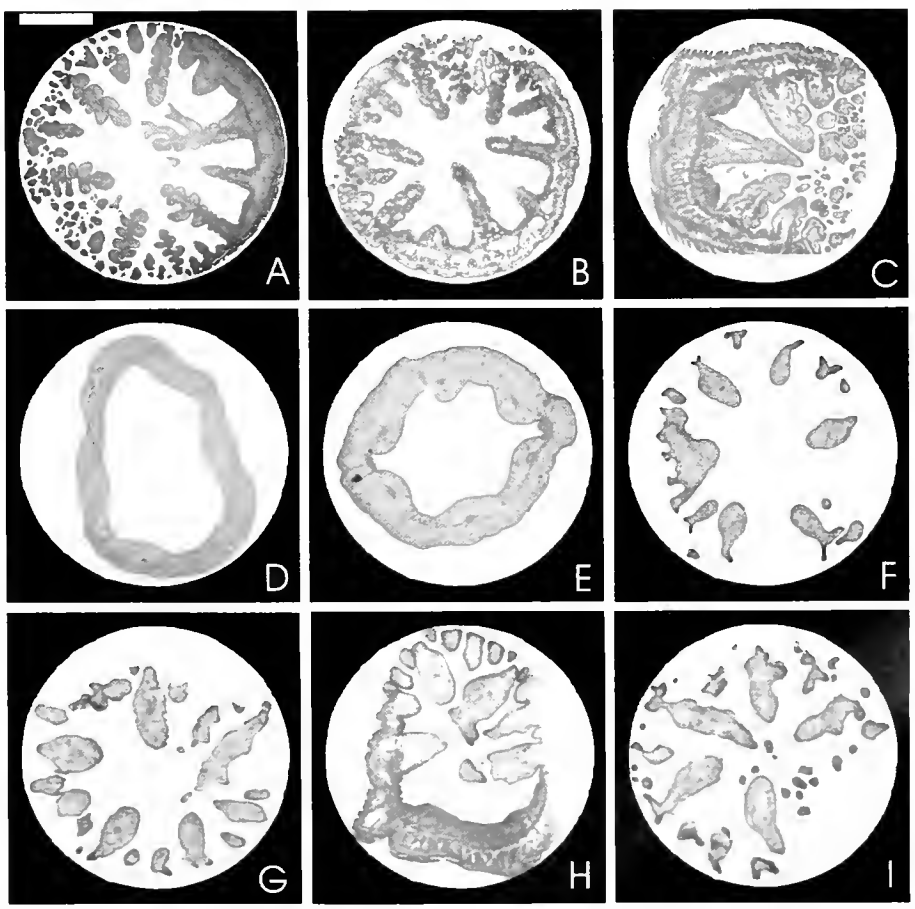

Figure 5. Regeneration of the inhalant siphon tip of *Donax hanleyanus*. A, B, and C: Intact siphon. D: Siphon wall immediately after amputation. E, F, G, H, and I at 1, 3, 5, 7, and 10 days after amputation, respectively. Scale bar: 1 mm.

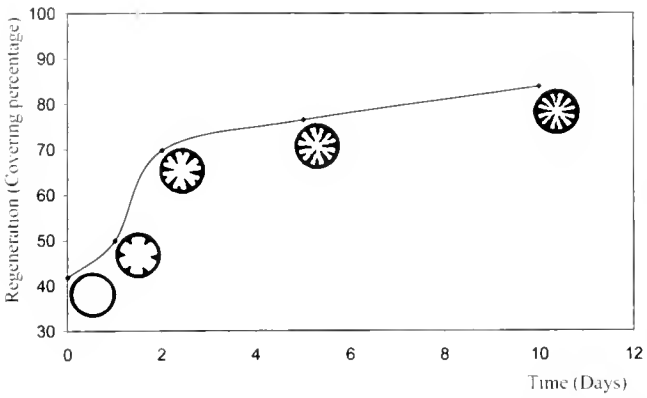

Figure 6. Rate of regeneration of the tentacle structure of the inhalant siphon of *Donax hanleyanus*. Each point is in correspondence with standardized drawings.

Wade 1969, Ansell 1983a, Ansell 1983b), although there is variation among members of the genus in the numbers of tentacles comprising each series (reflecting the number of siphonal nerves) and considerable variation in the complexity of their branching structure, especially around the tip of the inhalant siphon.

The study of siphon regeneration in bivalves is relevant to the impact of predation, mainly by fish and crabs, and the adaptations that bivalves require to survive to this impact (Edwards et al. 1970, Trevallion 1971, Lockwood 1980, Hodgson 1982a, Hodgson 1982b, Petersen & Quammen 1982, Pekkarinen 1984, de Vlas 1985, Ansell & Gibson 1990, Coen & Heck 1991, Bonsdorff et al. 1995, Ansell et al. 1999). The cropping of the siphons without killing the prey represents a way of conserving prey resources (i.e., it relaxes the predation pressure because it does not cause mortality) (Ansell 1983a).

The regeneration of the inhalant siphon in *D. hanleyanus* can be considered fully completed, in terms of siphonal function, between the fifth and the seventh day of regeneration. After this period the siphon continues growing in complexity and perhaps also in length, even beyond the tenth day. Hodgson (1982b) found that regenerating primary siphonal tentacles of *D. serra* could be detected as short lobes by 72 h following amputation. Within a further 24 h, these tentacles had elongated; by day 4 they had developed into tentacles, and secondary tentacles were also growing; by day 5, primary and secondary tentacles were large and multilobed, and tertiary tentacles were appearing; and by 7 to 8 days after amputation, the tentacles had attained their former size and appearance. Ansell et al. (1999) found very similar results for *D. vittatus*. *Tellina tenuis* da Costa, *Scrobicularia plana*, and *Macoma balthica* all lack elaborate siphonal tentacles, having only simple siphonal lobes. Hodgson (1982a) reports that these are fully reformed by 7 days after amputation in *S. plana*. In *M. balthica*, traces of the lobes are seen 2 days after amputation, and the lobes are fully formed again after 7 days (Pekkarinen 1984). The time course found here for the differentiation of the siphonal tentacles of *D. hanleyanus* was similar to that of *D. serra* and *D. vittatus*.

However, most of these studies concentrate on the later siphon regeneration, quantifying the regenerated tissue after months of amputation, and found that the siphon continues to grow at a rate that depends on the quantity of removed tissue at the beginning of the experiments. In *T. tenuis*, *S. plana*, and *D. serra*, regrowth proceeds at approximately 17–25% of the (undamaged) siphon weight per week (Hodgson 1982a), whereas the observations of de Vlas (1985) indicate a somewhat lower rate of regrowth in *M. balthica* of approximately 10% per week, with the regrowth rate proportional to the amount lost. Pekkarinen (1984) also found a relatively slow rate of regrowth for *M. balthica*; when one third of the siphon was removed, it took 3 mo to regrow to its normal size. The rate of regrowth was not measured for *D. hanleyanus* in this study but may be expected to be similar.

These authors also found that a lag period followed the first 24 h after the cut and point out that in this period there is a reorganization of connective tissue in the wound area. This is also seen in *D. hanleyanus* during the first 24 h after the cut; that is, the amputated siphon does not undergo any remarkable morphological change in this first period after amputation.

The evidence obtained from this study, together with the results of Hodgson (1982a, 1982b) Pekkarinen (1984), and Ansell et al. (1999), confirm that inhalant siphon regeneration is a universal process inherent to species belonging to the Tellinacea superfamily. Moreover, all the species studied up to now suggest that the regeneration rate is very similar regardless of latitude, temperature, and intensity of wave action.

SHELL GROWTH AND BIOMETRY OF THE STRIPED VENUS *CHAMELEA GALLINA* (L) IN THE MARMARA SEA, TURKEY

MEHMET CENGIZ DEVAL
Istanbul Üniversitesi, Su Ürünleri Fakültesi, Ordu Cad. No: 200. Laleli-Istanbul, Turkey

ABSTRACT Growth of the striped venus *Chamelea gallina* (L. 1758) in the northern Marmara Sea was studied by aging the shells. Internal growth bands with a seasonal pattern were identified on cross sections of the shell. During the period of reduced growth in October and February, a narrow hyaline band is formed. A large opaque band is formed between March and October. In the longest period of maximal growth, the increment coincides with the summer thermal maxima. *C. gallina* grows rapidly, reaching a length of 15 mm at the end of the first year and 21 mm at the end of the second year. At the end of the fourth and the fifth year, the length reaches 26 and 29 mm, respectively. The study of functional regressions permits us to conclude that the growth is allometric.

KEY WORDS: bivalve, *Chamelea gallina*, biometry, age, growth, Marmara Sea

INTRODUCTION

Growth rings on shell surfaces have been widely used to make inferences about age and growth rate in bivalves. However, in some species it is difficult to recognize real seasonal growth rings from false rings that may form under different stress conditions (e.g., storms, extreme temperatures, diseases, spawning, gonad development, dredging, etc.). (Polenta 1993, Deval 1995, Gaspar et al. 1995). Moreover, in older specimens the growth marks are so close to each other and to the shell margin that it may be difficult to identify them correctly.

Calcium carbonates and organic matter are deposited in the shell layers with a seasonal pattern (Panella & Mac Clintock 1968, Rhoads & Lutz 1980). In cross sections, these shell layers may be recognized by their optical characteristics and therefore are used to age bivalves.

Cross-sectioning has already been used successfully to age venerid clams (Richardson 1988, Ramon & Richardson 1992, Polenta 1993, Arneri et al. 1995). This method has also been used in the present investigation to study the growth of *Chamelea gallina* in the Marmara Sea. The most commonly used method to determine the rate of bivalve growth is to measure the changes in the dimensions of the shell. In the case of the striped venus *C. gallina*, the shell length along the anterior–posterior axis and the shell height measured from the umbo to the shell margin have been used.

C. gallina is found in throughout the Mediterranean Sea, including the Black Sea. Along the Atlantic coast of northern Europe it is replaced by the closely related species *C. striatula* (Backeljau et al. 1994). Both species are preferential, distributed on coastal fine sands (Guillou & Sariau 1985). *C. gallina* can be present in high densities in the Marmara Sea and in the Black Sea (Deval & Oray 1992, Deval 1995). The exploitation of *C. gallina* in Turkish waters started 14 y ago, and the yearly catch had reached 41 thousand tons by 1994. The striped venus plays an important role in the economy of Turkey, and this species is totally exported.

MATERIALS AND METHODS

Between February 1993 and April 1994 at approximately monthly intervals, samples of *C. gallina* were collected by dredging (Picard 1965) in depths of 4–7 m in a site off Tekirdag (Barbaros), in the northern Marmara Sea (Fig. 1). During the research period, 2,887 specimens were collected. Measurements of the length, height, width, total weight, shell weight, and meat weight were made with a vernier caliper, which was accurate to 0.1 mm, and with a digital balance, which was accurate to 0.01 g. The minimum and maximum values of the arithmetic mean, variance, coefficient of variance, and standard error (SE) were calculated, and the results were discussed (Valli et al. 1977, Valli et al. 1985, Valli et al. 1986). Log y = Log a + b. Log x logarithmic model, which could easily be turned into $y = a \cdot x^b$, was used for biometric changes of *C. gallina* (Ricker 1973, Ricker 1975).

Generally, for each 1-mm length class, five representative shells were sectioned. The right valve of the shell was cross-sectioned from the umbo to the ventral margin along the line of maximum growth, mounted on a glass slide, and then ground and polished on a lapidary wheel to obtain a section of approximately 20–30 μm. The section was then examined using a dissecting microscope under reflected light at low magnification. A total of 403 sections were prepared in this way and could be used for the interpretation of distinct annual increments. Shell sections were measured with video-analysis software, processing on a personal computer where the images were recorded through a video camera connected to the dissecting microscope. A complete record of size was obtained for each clam by measuring distance (height) from the umbo to the ventral margin of each hyaline band. Shell length was then transformed in shell height using the following regression:

$$\text{Length} = 0.491 + 1.062\ \text{Height}\ (r^2 = 0.996;\ n = 536)$$

In the Marmara Sea, *C. gallina* has a rather long spawning season, with a peak in June-July (Deval 1991). Therefore, to compute the parameters of the Von Bertalanffy growth equation June 1 was chosen as conventional birthday for all individuals considered in the length-at-age key:

$$L_t = L_\infty[1 - e^{-K(t-t_0)}]$$

where K is the Von Bertalanffy growth constant, L_∞ is the asymptotic maximum length, and t_0 is the age at time zero.

RESULTS

During the study, the minimum measured length and the maximum measured length were 3.6 mm and 34.5 mm, respectively. The mean length was found to be 20.1 ± 0.12 mm (±SE). The most common repeated values of length was 20 mm (by 6.8%), 19 mm,

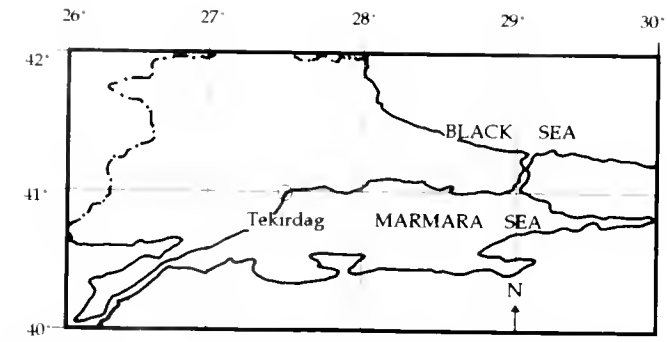

Figure 1. Location in the Marmara Sea where *Chamelea gallina* samples were collected.

and 21 mm (both by 6.6%). The length frequency distribution of *C. gallina* samples is shown in Figure 2.

The regression relationship for length and height with weight for *C. gallina* was positively linear. However, the relationship of the dimensional and the weight parameters (length/weight) was exponential. As seen in Table 1, when the regression coefficient between the two length variables (or the two weight variables) is $b \neq 1$, there is allometry in growth; when $b = 1$, there is isometry in growth. Likewise, when $b = 3$ between the length and growth variables there is isometry; when $b \neq 3$, there is allometry. Accordingly, between all variables there is an allometric growth.

Aging was carried out on 403 cross sections by two independent readers. Agreement was achieved on 297 shells (73.7%); the other shells were not further considered. To determine the periodicity in the formation of the hyaline band, the distance from the shell ventral margin to the nearest hyaline band was measured in all clams in the size range of 11–25 mm. When this distance did not exceed 1 mm, the hyaline band was considered "at the margin band" (Fig. 3). Of the 297 shells with hyaline bands, 198 shells had margin bands. The seasonal distribution of 198 *C. gallina* with bands at the margin of 11–25 mm is given in Table 2.

As seen Table 2, even though the building of the hyaline bands during the year is seen, the percentage of shells building hyaline bands in the warm summer season is very low (5.3%). However, the formation of hyaline bands appears to increase in the winter.

C. gallina in the Marmara Sea spawns from May to September, with a peak in early summer (Deval 1991). Therefore, individuals in the first winter of life exhibit quite different sizes. Specimens born earlier (in May) benefit from the appropriate conditions for rapid growth during the summer. By winter they may already have attained a length of 18–19 mm. However, specimens born at the end of the spawning season (August-September) benefit from the optimal environmental conditions. For a short period and in winter

TABLE 1.

Regression and confidence intervals of allometric growth for biometrics parameters of *Chamelea gallina*.

Variables (Dependent-Independent)	*n*	R	Log a	b	95% Confidence Intervals

MW-TW	42	0.807	−1.039	1.180	0.9056–1.4547

H = height; L = length; W = width; SW = shell weight; MW = meat weight; TW = total weight.

they may be only 2–3 mm in length. Usually in the following summer these specimens have an above-average growth rate. The growth rate has a high interindividual variability. A specimen of 19 mm in length may be 1–3 y old (Fig. 4; Table 3).

The routine included in the software package FISAT (Gayanilo et al. 1996) was used to estimate the parameter of the Von Bertalanffy growth equation, together with their asymptotic standard error.

$$L_\infty = 33.46 \pm 1.32 \text{ mm} \qquad K = 0.37 \pm 0.067 \qquad t_0 = -0.69 \pm 0.30 \text{ y}$$

The theoretical mean length at age and the annual growth computed according to the above parameters of the Von Bertalanffy growth equation are listed in Table 4.

In the northern Marmara Sea, *C. gallina* has a rather rapid growth during the first 2 y of life (Table 4) and reaches the minimum marketable length of 23 mm in less than 3 y. The live-weight annual increment is highest during the third year of life (Fig. 5). Growth rates, both in length and weight, are much lower in older individuals, and the maximum size attained in the Marmara Sea is significantly lower than in the Adriatic Sea. The mean life span in the *C. gallina* population of the northern Marmara Sea seems not to exceed 5 or 6 y (shell length 29–30 mm). Only 2.2% of the sampled specimens were larger than 30 mm, indicating a rather high exploitation level in the investigated area.

DISCUSSION

This research is the first analysis on the growth and age of *C. gallina* in the Marmara Sea, giving the most detailed biometric parameters of *C. gallina* in Turkey.

7	31.4	0.9	9.14	0.74

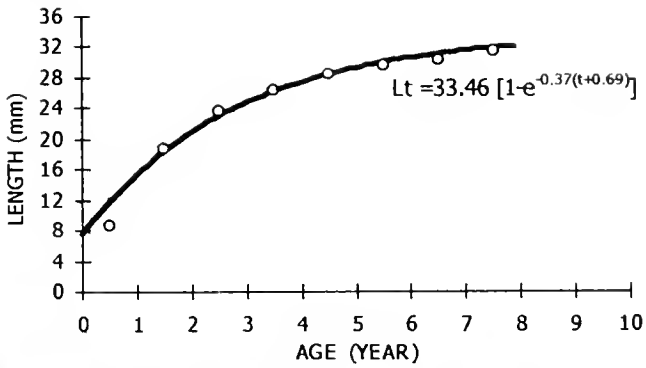

Figure 5. V. Bertalanffy growth curve of *Chamelea gallina* in the Northern Marmara Sea.

The investigations conducted on the biometric parameters in Turkey reported the maximum length of *C. gallina* as 36 mm in the Dardanellas (Alpaz & Önen 1989), 35.5 mm in northern Marmara Sea (Cebeci 1992), and 32.2 mm in western Black Sea coast (Deval 1991). Many studies performed on *C. gallina* showed a higher maximum length of the specimens sampled in Europe and in the Mediterranean. The maximum length of *C. gallina* was 41 mm in the coast of Spain (Vives & Suau 1962), 49 mm in the middle Adriatic Sea (Polenta 1993), and 46 mm in the southern Adriatic (Marano et al. 1982).

By analyzing the relationships between the weight and the dimensional parameters, calculated from regression and correlation analyses, the growth was determined to be allometric. The growth of *C. gallina* studied on the coast of Spain and in the sea of Adriatic was also allometric (Pogiani et al. 1973, Marano et al. 1982, Cano & Hernandez 1988).

The hyaline and the opaque growth bands were clearly evident in cross sections of valves from *C. gallina* from the Marmara Sea. These growth bands appeared to be formed seasonally and were used to age clams and to establish a length-at-age key. The parameters of the Von Bertalanffy growth equation calculated from these data, together with the size frequency distributions obtained from the monthly sampling program, show that *C. gallina* in the Marmara Sea has a lower growth rate and attains a smaller size in comparison with other Mediterranean areas.

In the Marmara Sea the annual growth pattern, characterized by reduced or no growth during the winter months with sea temperatures below 10°C, is similar to that reported for the Adriatic Sea (Froglia 1975, Polenta 1993, Arneri et al. 1995). In both areas a hyaline band is formed in the shell during winter months. In the western Mediterranean, off the southern coast of Spain, reduced growth and formation of the hyaline band were observed late in summer (Ramon & Richardson 1992), and apparently temperatures above 27°C negatively affect the growth of *C. gallina*.

Table 5 lists the average lengths at age reported in the literature for different Mediterranean locations. Although different authors used different methods to study the age and growth of *C. gallina*, the results obtained in different Adriatic regions are in agreement that, in the Mediterranean Sea, the most growth occurs in the first four age classes. The maximum sizes recorded by Adriatic workers are well above those reported for Spanish and Turkish *C. gallina* populations.

The differences in the growth rates of *C. gallina* off the Spanish, Adriatic, and Marmara coasts could be related to environmental factors such as annual sea temperature and salinity. *C. gallina*

TABLE 5.

Average lengths at age of *Chamelea gallina* reported in the literature for different Mediterranean localities.

Reference	Region	Method	Age (y)								Maximum Length
			1	2	3	4	5	6	7	8	
Poggiani et al. (1973)	Middle Adriatic	Surface rings	15	24	30	33	35				46
Froglia (1975)	Middle Adriatic	Length distribution	17	25							
Polenta (1993)	Middle Adriatic	Internal bands	17	25	30	34	38	39	42	45	49
Marano et al. (1982)	South Adriatic	Surface rings	15	23	31	35	38	42			46
Vives and Suau (1962)	West Meditter.	Surface rings	18	24	28	31

Present investigation	North Marmara	Internal bands	15	21	25	27	29	30			34

has the highest growth rate in the Adriatic eutrophic waters. The lowest growth rate was observed in the population of the northern Marmara Sea (off the Tekirdag coast). Water masses of low salinity flow from the Black Sea to the Mediterranean Sea through the Marmara Sea (Kocatas et al. 1993). Therefore, the salinity over the Chamelea fishing grounds in the Marmara Sea (17–24‰) is significantly lower than in Adriatic and Spanish coastal waters (32–36‰). At the moment no experimental data are available to relate the different halide regimes to the observed differences in growth.

In conclusion, *C. gallina* reaches 15 mm at the end of the first year and 21 mm at the end of the second year. The regulations on the fishery of this species restrict the catch of individuals less than 22 mm (corresponding to 24 mm in length), and *C. gallina* reaches this height around the end of the third year (Fig. 5). The estimated growth coefficient and asymptotic maximum size were 0.37 and 33.46 mm, respectively.

DISTRIBUTION, ABUNDANCE AND SOME POPULATION CHARACTERISTICS OF THE OCEAN QUAHOG, *ARCTICA ISLANDICA* (LINNAEUS, 1767), IN THE MECKLENBURG BIGHT (BALTIC SEA)

MICHAEL L. ZETTLER,[1]* REGINE BÖNSCH,[2] AND FRITZ GOSSELCK[2]

[1]Baltic Sea Research Institute, Seestr. 15, D-18119 Rostock, Germany; [2]Institut für Angewandte Ökologie GmbH, Lindenweg 2, D-18184 Neu Broderstorf, Germany

ABSTRACT In the Mecklenburg Bight (western Baltic Sea), the ocean quahog, *Arctica islandica*, constitutes the most important species below the halocline. In 1999 a benthos survey at 95 stations in the Mecklenburg Bight showed a wide distribution of *A. islandica* at depths between 15.6 and 29.6 m. Mean abundance at these depths was 91 ind./m^2 with a biomass (AFDW) of 15 g/m^2. Maximum densities observed at these depths were 571 ind./m^2 and 120 g/m^2, respectively. The Mecklenburg Bight had an estimated colonized area of 5200 km^2 and a total annual production of 26500 t AFDW. In comparison to a data set of the 1960's, we found an increased quahog population. Ocean quahogs ranged from 1.5 to 64 mm in shell length and from 1 to 70 years of age. Growth was relatively slow for the first 40 years. Most (90%) individuals in the population measured <30 mm shell length, indicating strong recruitment in the Bight during the past decades. While the highest abundance (most juveniles) was observed in depths between 15 and 20 m, maximum biomass (due to adults) lay between 20 and 25 m. Probably the recruitment zone was displaced from below 20 m to 15–20 m depth in the last decades. Mean quahog wet meat yields was 18.3%. The individual ash free dry weight decreased significantly with increasing shell length from 14.3% (<10 mm) to 9.4% (>40 mm). All results were compared with data from populations in North Atlantic and adjacent waters.

KEY WORDS: *Arctica islandica*, ocean quahog, distribution, abundance, growth, size, meat yield, Baltic Sea, Mecklenburg Bight

INTRODUCTION

The ocean quahog, *Arctica islandica*, is an arctic-boreal species that occurs in North Atlantic and adjacent waters. In the North Sea region, the species' range extends into the Western Baltic Sea and reaches its eastern limit of distribution in the Arkona basin (von Oertzen and Schulz 1973). The largest populations reside in Kiel and Mecklenburg Bights. The ocean quahog is the largest bivalve in the Baltic Sea and lives for more than several decades (Arntz and Weber 1970, Brey et al. 1990). The long living species is an important indicator for environmental conditions. Beside salinity and sediment structure, oxygen concentration has a strong influence on the composition of Baltic Sea fauna and flora. Since the 1960's, oxygen deficiency below the halocline (16 to 20 m) has resulted in destruction of the bottom fauna of Mecklenburg Bight (Gosselck et al. 1987, Schulz 1968). Although *A. islandica* is highly resistant to oxygen depletion, the population is diminished by mortality caused by frequent and long lasting periods of anoxic conditions. In the deeper parts of Lübeck and Mecklenburg Bights a severe decrease of the Baltic Sea population of *Arctica islandica* has resulted during recent decades (Gosselck et al. 1987, Schulz 1968). Long living species like the ocean quahog (*Arctica islandica*) decreased in abundance and were replaced by communities of short living polychaetes (spionids, capitellids).

The geographical variability in growth rates of *A. islandica* is well documented for the North Sea and adjacent waters (Witbaard et al. 1999) and for US and Canadian east coasts (Kennish et al. 1994, Kraus et al. 1992, Murawski et al. 1982). Much is known about the reproduction, meat yield and age mostly for Atlantic populations off North America and Iceland coasts (e.g. Chaisson and Rowell 1985, Fritz 1991, Steingrimsson and Thorarinsdottir 1995, Thorarinsdottir and Einarsson 1996). Little is known about populations of this species in the vicinity of the Baltic Sea (Arntz and Weber 1970, Brey et al. 1990). The purpose of this study was to investigate the distribution, frequency and biomass of the recent population of *Arctica islandica* in Mecklenburg Bight as the first extensive study on the population characteristics of this important indicator species near its limit of distribution. A further aim was to compare these results with existing data from the 1960's compiled by Schulz (1969a) and to include an 11-year time series of one monitoring station.

Area of Investigation

The Mecklenburg Bight is part of the Belt Sea and belongs to the transition area between the North Sea and Baltic Sea (Fig. 1). It is connected with Kiel Bight via Fehmarnbelt and with Kattegat via the Belts. To the East, the Kadet trench crossing the Darsser rise connects it with the Baltic proper.

The location in the southwestern part of the Baltic with its relatively high salt content is decisive for benthic colonisation. Fauna and flora of the area are determined by hydrological and morphological factors, with salinity being the formative influence. Another important factor is the sediment structure, which is formed by residual sediments and mud.

During 1999 a macrozoobenthos survey was made in the Mecklenburg Bight. In total 95 stations were sampled between March and September (Fig. 1). The depth interval was 5 to 29.6 m, the sediment varied from fine sand at the shallowest stations to sand mixed with silt and clay at deepest stations. The sediment characteristics and current data within the area were published by Lange et al. (1991).

MATERIALS AND METHODS

Profiles of salinity were recorded throughout the water column using a CTD (conductivity/temperature/depth probe) system.

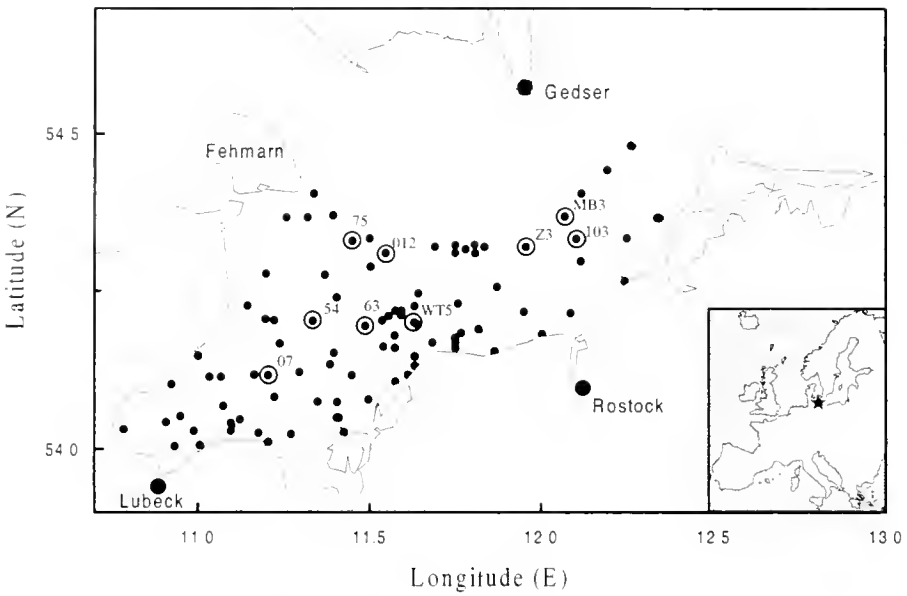

Figure 1. Investigation area with 95 stations in the Mecklenburg Bight (encircled stations refer to text and figures).

Samples for bottom water oxygen were taken with a 5 l water sampler (mounted on the CTD) at 0.5 m above the bottom and were determined with Winkler titration. Benthic samples were taken with a 0.1 m^2 Van Veen grab. At each station three parallels of grab samples were carried out. Due to sediment conditions grabs of different weights were used. The samples were sieved through a 1 mm screen and animals preserved with 4% formaldehyde in the field. For sorting in the laboratory, a stereo microscope with 10-40× magnification was used. A dredge haul (net mesh size 5 mm) was taken in order to obtain *A. islandica* specimens for the study of population size structure. For the characterisation of the habitats, i.e. assessment of sediment structure, epibenthos and current, an underwater video-system was used which was mounted on a sledge. The sledge was towed over the bottom by a drifting vessel at lowest possible speed (< 1 knot). The camera was installed on a pan and tilt head. Scaling was accomplished by four crossed laser beams projected into the picture. In addition bivalve siphon openings detectable at the sediment surface were counted to assess patchiness and distribution of adult (approximately >30 mm shell length) ocean quahogs.

At each station the shell length of all collected individuals of *A. islandica* were measured with a vernier calipers to the nearest 0.1 mm for the length-frequency distribution and the length-meat weight relationship. In total about 2300 specimens were measured. The valves and the wet meat of the specimens were weighed separately. Furthermore, the dry weight (DW) and ash free dry weight (AFDW) were determined to the nearest 0.01 mg. Because of very low weights, quahogs with shell lengths <3 mm were weighed in groups of 5 or 10 individuals sorted in size classes of 0.1 mm. Length-frequency distribution for each station was calculated for 10 mm size classes. The age of each *A. islandica* was estimated by measuring internal growth bands in the shell. This method is only applicable for specimens younger than 40 years (nearly all observed individuals are younger). For comparison and calibration, several shells were processed for observation of internal growth lines in acetate peels (see Ropes 1985).

The distribution map of the ocean quahog in the Mecklenburg Bight was made using Surfer (Win32) version 6.04 program of Golden Software Inc. The recent distribution was compared with the results from Schulz (1969a), whose data were transformed into the Surfer program to obtain a comparable map. Quahog distributional data from the monitoring station 12 of the Baltic Sea Research Institute Warnemuende and the Institute of Marine Research Kiel were used for the 11-year time series (1988–1999).

RESULTS

Bottom Water Variables

Salinity ranged between 7.5 and 22 psu in the water column. Bottom water salinity of areas inhabited by *Arctica islandica* varied between 12.5 and 22 psu in 1999. No oxygen deficiency was observed during our survey. Up to a depth of 16 m more than 7 mg/l were measured. Oxygen content decreased to a minimum of 4.5 mg/l only in the deepest parts of the Bight.

Distribution, Abundance and Biomass

In 1999 *Arctica islandica* was distributed between 15.6 and 29.6 m in the Mecklenburg Bight. Most stations within these depths were colonized (Fig. 2). Only in the deepest parts of the innermost area (Lübeck Bay) were no quahogs found. Furthermore, the outer Kadet trench with strong currents and stony substrates was not inhabited. The highest abundance was found in the south-eastern part of the Bight with a maximum of 571 ind./m^2 and an AFDW of 34 g/m^2 at station 103 (water depth 17.4 m). Thirty years ago (in the mid 1960's), *A. islandica* reached an abundance between 10 and 100 ind./m^2 with a maximum of 200 ind./m^2 in the central part of the Bight (Schulz 1969a) (Fig. 2). At depths below 20 m of the innermost area (Lübeck Bay), no *A. islandica* were found. The highest biomass (AFDW) was observed in deeper parts of the central Bight at station 54 (water depth 23 m) with 120 g/m^2 and an abundance of 236 ind./m^2 (Fig. 3). The Mecklenburg Bight had an estimated colonized area of 5200 km^2 within water depths of 15 and 30 m, a mean abundance of 91 ind./m^2 and a biomass (AFDW) of 15 g/m^2. Based on these values, the whole population

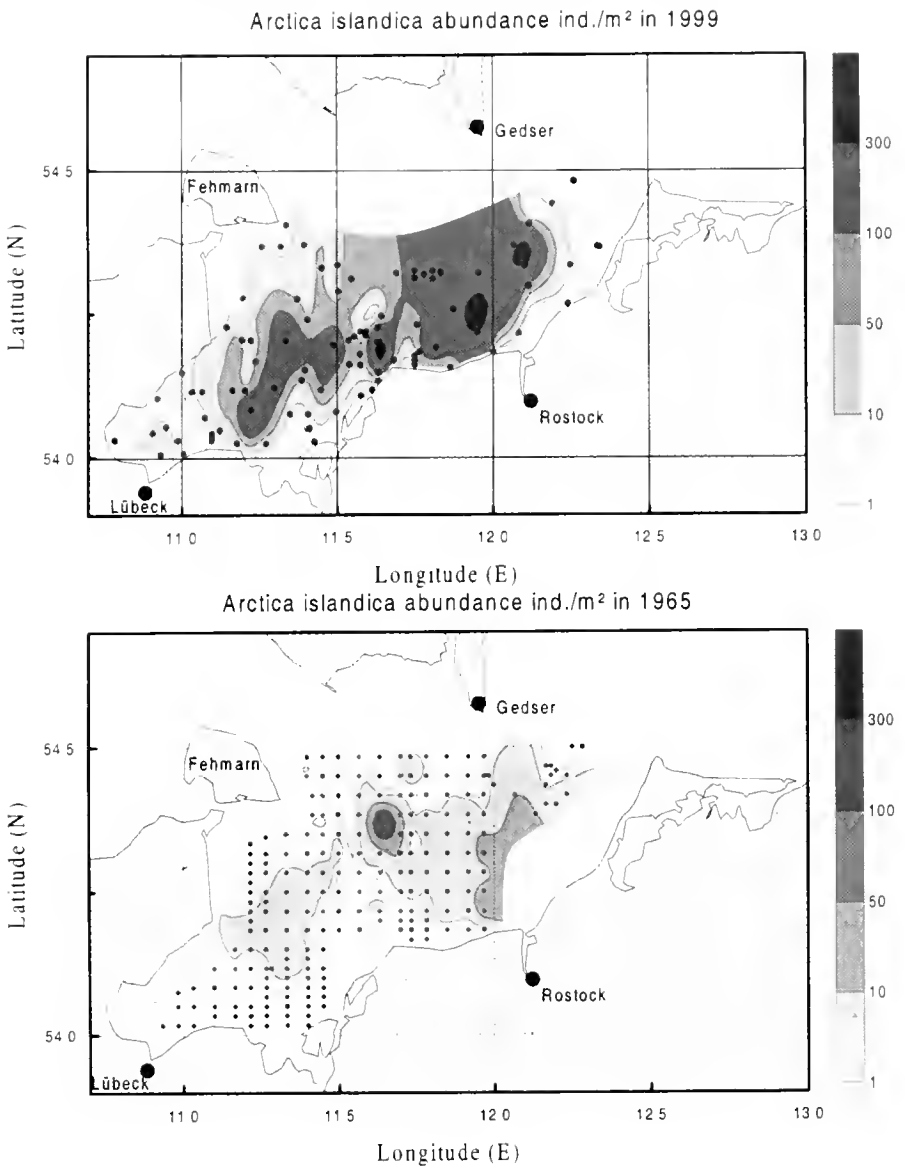

Figure 2. Distribution of *Arctica islandica* (ind./m²) in 1999 and during the investigation period in the mid 1960's of Schulz (1969a) (same scale for better comparison).

of the Bight was estimated at approximately 4.7E + 11 individuals with a biomass (AFDW) of 7.8E + 04 t (1.04E + 06 t wet weight).

In 1965 the mean abundance reached 20 ind./m². In the last 11 years the abundance of *A. islandica* at station 12 varied between 20 and 120 ind./m² (Fig 4). *A. islandica* occurred in mean density of 40 to 75 ind./m². However, due to patchy distribution of this species, the standard deviation was very high. The same was observed in 1999, when the highest abundance occurred with 120 ± 70 ind./m². Similarly, records by the video showed a similar patchy distribution of the quahog siphon openings. If only adults, specimens were taken into account, the average counts of openings were comparable with the estimated abundance by grabs at several stations. However, due to patchiness, the maximum abundance was much higher and ranged between 400 and 700 ind./m². Between these colonized centers, big patches of unsettled sediments were visible.

In this study the highest abundance was observed in depths between 15 and 20 m, whereas the maximum of biomass occurred between 20 and 25 m (Fig. 5). With increasing water depth, the abundance decreased from an average of 155 ind./m² in 15-20 m, to 85 ind./m² in 20 to 25 m, and 35 ind./m² in 25 to 30 m, respectively. In comparison the biomass (AFDW) was low in both the 15 to 20 m, and 25 to 30 m interval (7–9 g/m²), but averaged 28 g/m² at 20 to 25 m.

Population Structure, Meat Yield and Growth

During the benthos survey, shell lengths of *Arctica islandica* were between 1.5 and 64 mm (Fig. 6). Quahogs in the size class 0 to 10 mm composed 40% of the population. Particularly at shallower stations (15–20 m), the one- or two-year size classes (<10 mm) dominated. In deeper water (>20 m) individuals >20 mm were the dominant group. Generally only one size class dominated the population structure of an area. At shallow stations (stns WT5, MB3 and 103, see fig. 1 and 6) the most successful settlement took place during the last two years (the size class 0 to 10 mm domi-

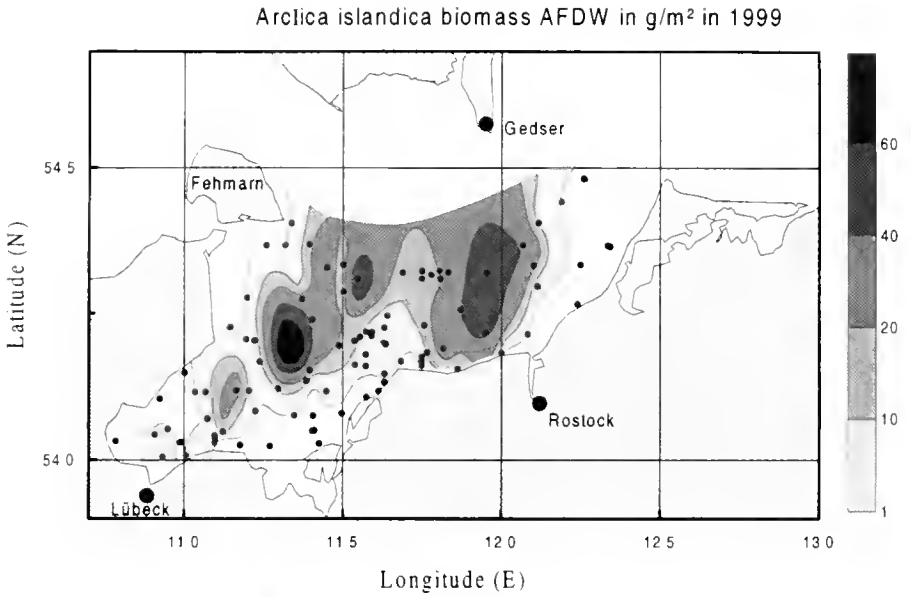

Figure 3. Biomass distribution of *Arctica islandica* (g AFDW/m²) in 1999.

nated with over 50%), whereas little or no recruitment was detected in stations deeper than 20 m. The dominant size class varied from 11 to 20 mm at stations 12 and Z3 via 21 to 30 mm at stations 63 and 07, to 31 to 40 mm at stations 75 and 54 (Fig. 6).

The wet meat yield (percentage of total wet weight) increased with increasing size up to shell length of 55 mm (Fig. 7). The mean meat yield of all individuals (1.5–55 mm) was 18.3% and varied between a minimum at 5% (2.7 mm shell length) and a maximum at 38% (47 mm shell length).

The organic content (all organic material of a quahog, i.e. meat, periostracum and ligamentum) was calculated as the relation of individual ash free dry weight to dry weight (Fig. 8). With increasing shell length a significant decrease in organic content was observed. The highest amount (14.3%) appeared in the shell size class <10 mm. The lowest organic content was 9.4% in the size class >40 mm. The mean organic content of DW of all individuals (1.5 to 55 mm shell lengths) ranged from 7.1% to 22.3% with a mean value of 11%.

Relationship between shell length and individual weight (meat wet weight and ash free dry weight) is shown in Figure 9. In these graphs all measured specimens (1.5–64 mm) of all stations are included. The smallest meat wet weight was 0.095 mg at a shell length of 1.5 mm and the largest was 14.7 g at 64 mm (Fig. 9a). The average meat yield per unit shell length of *Arctica islandica* is indicated by the estimated mean regression line. Differences between the station means were not statistically significant. The ash free dry weight varied between 0.1 mg (1.9 mm in length) and 1.6 g (64 mm in length) (Fig. 9b). The estimated regression lines of the different populations (stations) did not differ significantly. The results indicate that quahogs throughout the Mecklenburg Bight approximately contained the same meat per unit shell length for the range of length considered.

Growth was estimated by measuring internal growth bands in the shell. The corresponding equation for the calculated best-fit regression lines for all included individuals (1.5 to 55 mm) given in Figure 10. The oldest measured specimen reached an age of

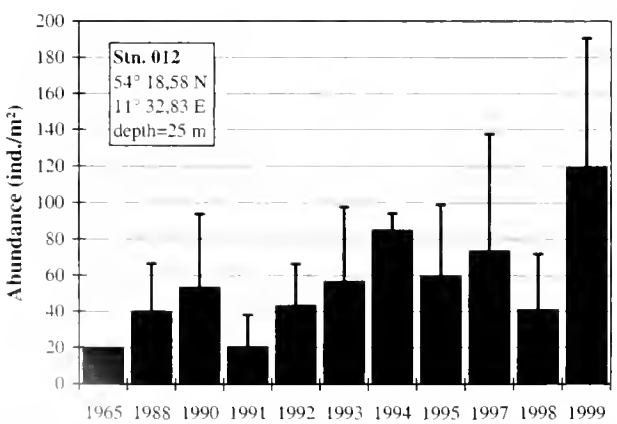

Figure 4. The development of mean abundance (± SD) of *Arctica islandica* at station 12 in the last 11 years in comparison with data of (Schulz 1969a) from the mid 1960's.

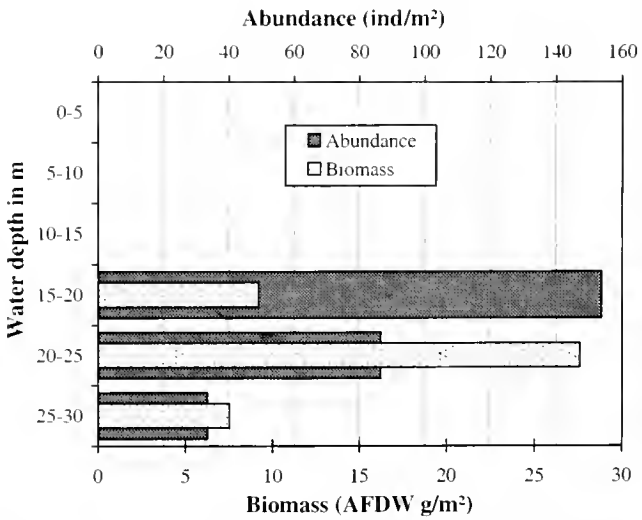

Figure 5. The vertical distribution of abundance (ind/m²) and biomass (AFDW g/m²) of *Arctica islandica* in 1999.

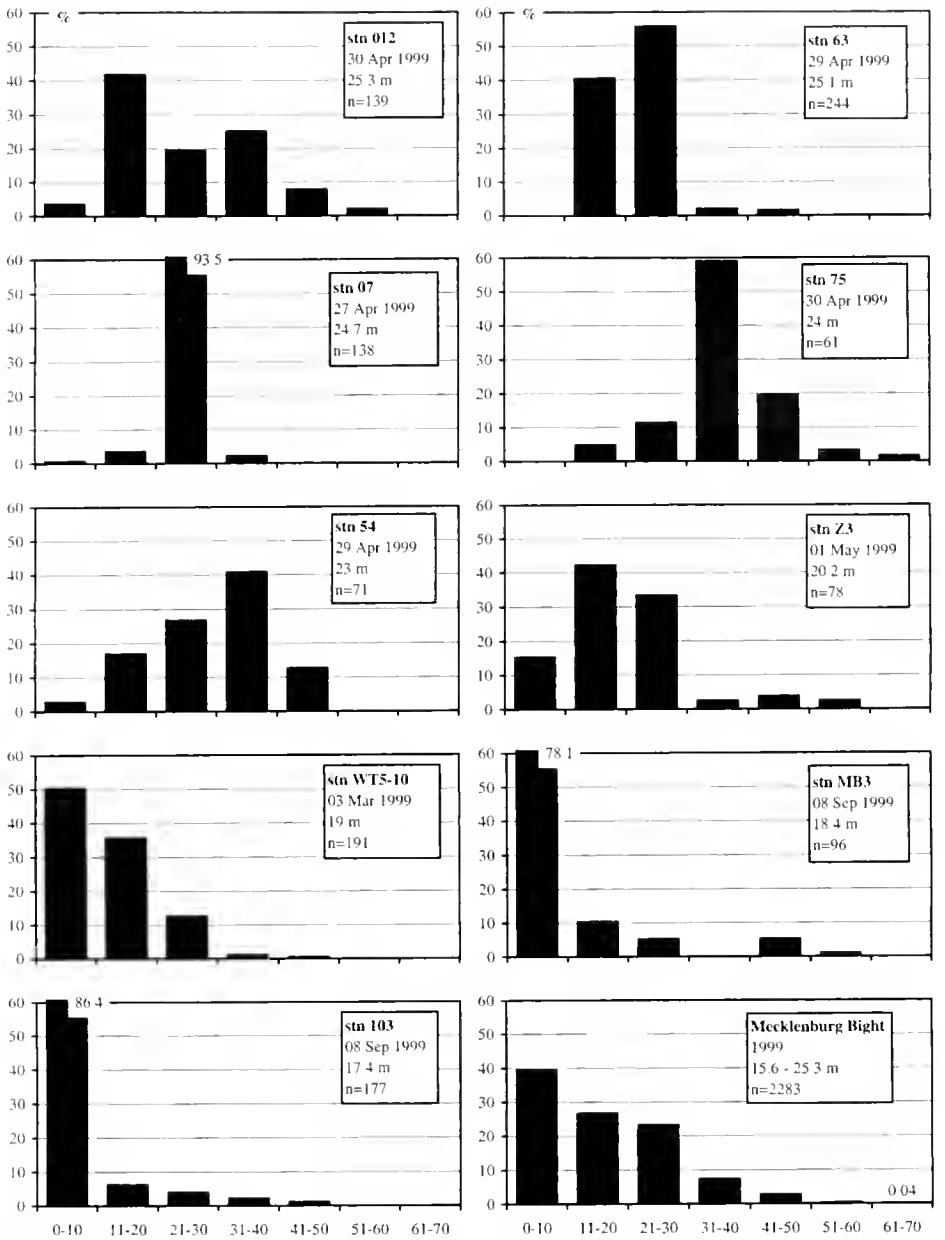

Figure 6. Shell length-frequency distribution for 10 mm size classes of *Arctica islandica* at several stations in depths between 17.4 m and 25.3 m in Mecklenburg Bight in 1999.

approximately 40 years. The largest and oldest specimen (64 mm) was not included because of difficulty of age estimation. After the equation, we got an age of app. 70 years.

DISCUSSION

The occurrence of *Arctica islandica* in the Mecklenburg Bight has been known since the last century when the first investigations on benthic fauna of the Baltic Sea took place (Boll 1852, Lenz 1875). While the main Baltic populations live in the Bay of Kiel and in parts of Sound and Belt, the distribution in the Mecklenburg Bight and the Arkona Basin represent the most eastern occurrence of this species in the Baltic Sea (von Oertzen and Schulz 1973). Due to the decreasing salinity in areas east of Mecklenburg Bight *A. islandica* has its natural limit of distribution there. Several investigations on biology and ecology of *A. islandica* of the Kiel Bay have been conducted (e.g. Arntz and Weber 1970, Brey et al. 1990, Oeschger and Storey 1993). However, information from the Mecklenburg Bight is very scarce (e.g. Al-Hissni 1989, Köhn 1989, Prena et al. 1997). Hagmeier (1930) observed a high biomass of *A. islandica* (195.1 g/m^2 fresh weight) in the Mecklenburg Bight during the 1920s, which is comparable with present biomass estimations. He found mostly adult specimens with juveniles scarcely occurring. The investigations of Schulz (1969a, b) at the end of the 1960s give the distribution pattern of *A. islandica* in the Mecklenburg Bight which was used for comparison with the present study. In the 1960s densities were low (20 ind./m^2 in mean). During the 1980s the abundance of the ocean quahog decreased in this region due to a long period of oxygen depletion (Gosselck et al. 1987,

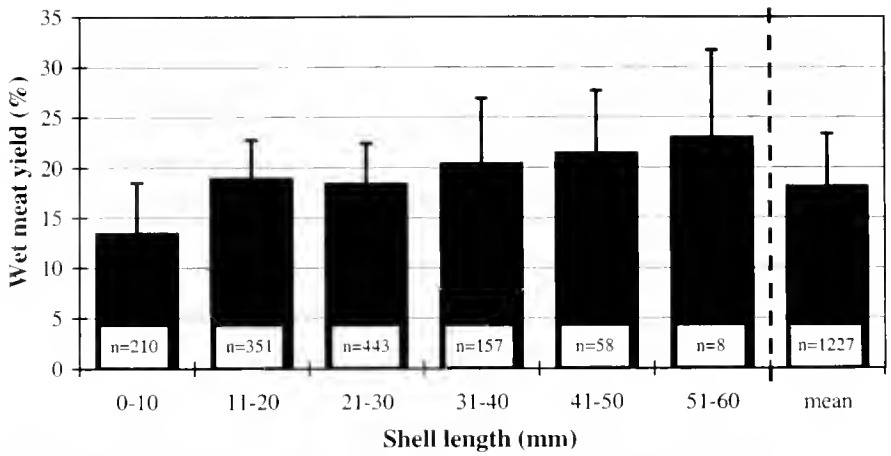

Figure 7. Mean wet meat yield in 10 mm size classes of *Arctica islandica* from the Mecklenburg Bight in 1999 (± SD).

Prena et al. 1997). In the inner part of the Lübeck Bay, in the 1980s no quahogs were found. In the early 1990s, the density of *A. islandica* increased in some regions of the Mecklenburg Bight (Al-Hissni 1989, Köhn 1989, Prena et al. 1997). Recently, a mean abundance of approximate 91 ind./m^2 in depths between 15 and 30 m occurred. The highest abundance was observed in the region between 15 and 20 m, whereas the maximum biomass occurred in deeper zones. Below the halocline, *A. islandica* is the most important species in the Mecklenburg Bight with respect to biomass. The mean biomass reached 15 g/m^2 AFDW (200 g/m^2 fresh weight). Brey et al. (1990) gave a P/B ration of 0.34 for populations in the Kiel Bay. If this ratio is applicable for the Mecklenburg Bight, the average annual production (AFDW) below the halocline amounts to 5.1 g/m^2. The total production of the Mecklenburg Bight is approximate 26500 t AFDW per year.

The different maximum zones for abundance and biomass are probably a result of recruitment failure in the deeper anoxic regions. In the deeper parts, oxygen depletion in late summer prevents the successful recruitment and growth of the juveniles, which settle mostly in summer and fall (Mann and Wolf 1983, von Oertzen 1972). The high biomass in the deep regions is based on adults (low numbers) that are able to survive critical times of oxygen depletion. *Arctica islandica* is one of the most tolerant species to oxygen deficiency and to hydrogen sulphide (von Oertzen and Schlungbaum 1972, Oeschger and Storey 1993, Theede et al. 1969). Nevertheless, Weigelt (1991) and Schulz (1969b) stated that possibly the high tolerance to oxygen deficiency is restricted to the adults, whereas the juveniles are more susceptible. Therefore, recruitment takes place only in favorable years. In the shallower zones (between 15 and 20 m), no major hypoxic episodes have been observed in the recent past (Matthäus et al. 1999). Although recruitment can take place in the shallower areas, conditions for growth are sub-optimal, probably due to the lower nutrition supply, lower salinity and higher temperature. The optimal temperature-range for fertilization, growth and survival of larvae and juveniles is 10° to 15° C (Landers 1976). Possibly the growing eutrophication of the western Baltic Sea explains the increased *A. islandica* population (see Arntz & Weber 1970, Persson 1987) and the displacement of the recruitment zone from below 20 m to the 15 to 20 m depth region.

The largest quahogs found were 64 mm long. In the 1960's Schulz (1969b) pointed out that only few specimens between 60 and 100 mm occurred in the central part of the Bight and juveniles were only found around 18 m depth. In this study sizes above 70 mm were observed only as empty shells. The most frequent size classes were 1.5 to 30 mm which included >90% of the *A. islandica* population of the Mecklenburg Bight. This population structure is completely different from populations of the Atlantic Ocean, where the smaller size classes are mostly absent (e.g. Fritz 1991, Murawski et al. 1982, Thorarinsdottir and Einarsson 1996, Steingrimsson and Thorarinsdottir 1995). We attribute this to successful recruitment in the Mecklenburg Bight during the last 10 to 15 years. In contrast in Atlantic waters, ocean quahog populations have only sporadic recruitment and strong recruitment events occur only every twenty (or more) years (Murawski et al. 1982, Steingrimsson and Thorarinsdottir 1995).

The mean wet meat yield of *A. islandica* of 18.3% (5% to 38%) is similar to other reported values. For a population in the Kiel Bay, Arntz and Weber (1970) reported a percentage of 19.3 to 22.2 with minimum values in winter. The meat yield of *A. islandica* off Iceland coasts ranged between 17% and 40% and averaged 30% (Thorarinsdottir and Einarssson 1996). If only the smaller size classes (<40 mm) of quahogs off Iceland are considered, then the mean wet yield of approximately 20% is similar to the result of this study. The meat yield observed from grounds off the coast of the United States and Canada ranged between 20.7% and 23% (Bakal et al. 1978, Chaisson and Rowell 1985).

In the Mecklenburg Bight, the mean individual ash free dry weight of *A. islandica* decreased from 14.3% to 9.4% with increasing size classes. The increasing mean wet yield and the decreasing

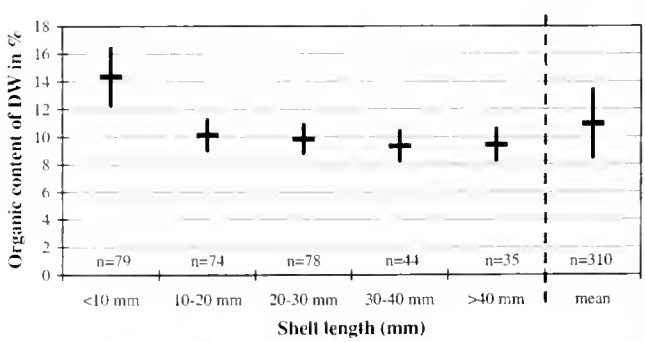

Figure 8. Mean individual percentage of ash free dry weight for different size classes of *Arctica islandica* from the Mecklenburg Bight in 1999 (± SD).

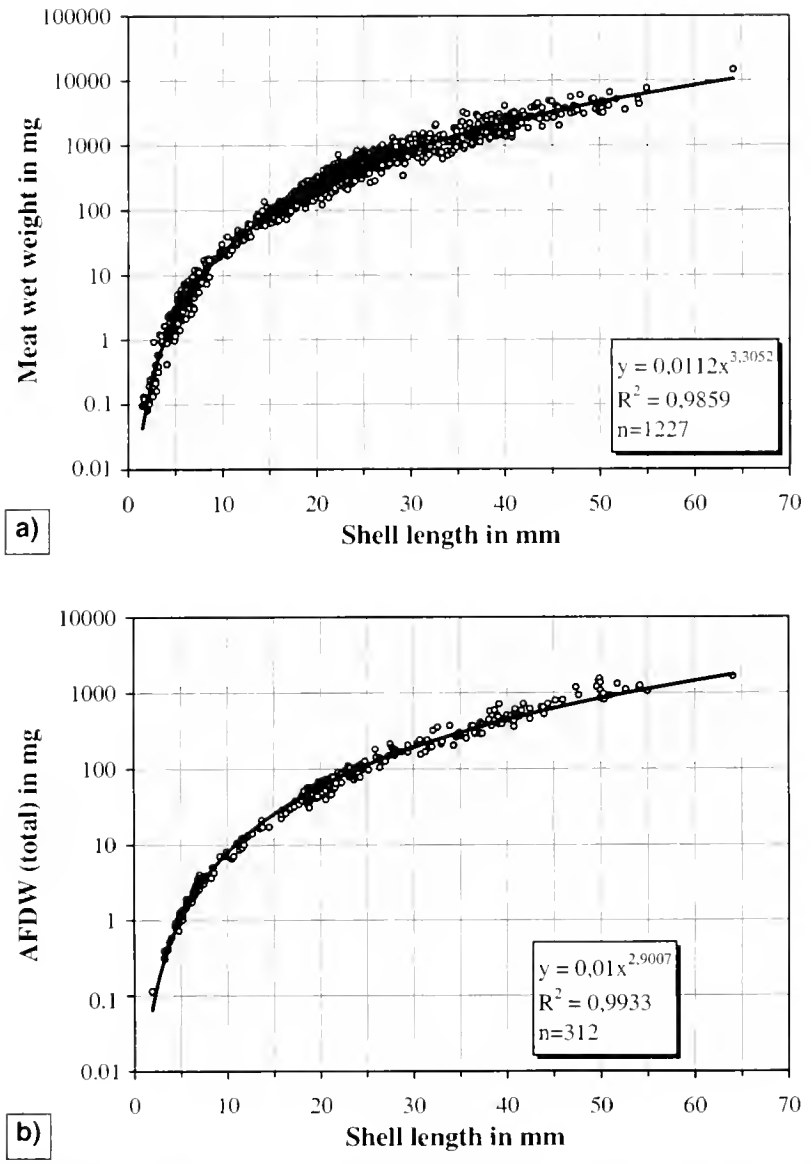

Figure 9. a) Estimated shell length-meat wet weight relationship for *Arctica islandica*, b) estimated shell length-ash free dry weight relationship for *Arctica islandica*. In these graphs all measured specimens of the whole Mecklenburg Bight populations are included. The corresponding equations for the calculated best fit regression lines is given in the figure.

ash free dry weight with increasing shell length indicate relatively higher water content of bigger quahogs. The length specific meat wet weight (shell-length to meat-weight relationship) in this study was similar to that reported for ocean quahogs off United States coasts. In the Mecklenburg Bight, the calculated meat wet weight for an individual of 95 mm shell length was 39 g. The meat wet weight of *A. islandica* off New York reported by Murawski et al. (1982) were 36 and 38 g and off New Jersey 37.9 and 51.3 g (Fritz 1991). The biggest meat wet weights of *A. islandica* ever reported (47.6, 55.5 and 70 g) were found off Iceland by Thorarinsdottir and Johannesson (1996). The calculated AFDW for an individual of 95 mm shell length reached 5.4 g.

Several authors reported on geographical differences in growth rates of *A. islandica* in its distribution area and between field and laboratory populations (e.g. Brey et al. 1990, Fritz 1991, Josefson et al. 1995, Kennish et al. 1994, Kraus et al. 1992, Steingrimsson and Thorarinsdottir 1995, Witbaard 1996, Witbaard et al. 1999). Ocean quahogs are among the slowest growing and long-living marine bivalves (Murawski et al. 1982, Thompson et al. 1980). Growth rates for this species vary with respect to location (temperature, food supply, salinity, and abundance). Kraus et al. (1992) observed the fastest growth in the laboratory where *A. islandica* reached 54 mm from 9.6 mm within three years. In the laboratory the specimens grow to 37 mm within two years. In the field they need 26 to 33 years to achieve the same shell length. The comparison of the growth curve of the Mecklenburg Bight population with growth curves calculated by Witbaard et al. (1999) for 12 populations from the North Sea and adjacent waters shows similar growth increments for the first 40 years of life. For the first five years, the Mecklenburg Bight population had a growth rate very similar to populations of the Kattegat with approximate linear increase in size with age (Josefson et al. 1995). In comparison with

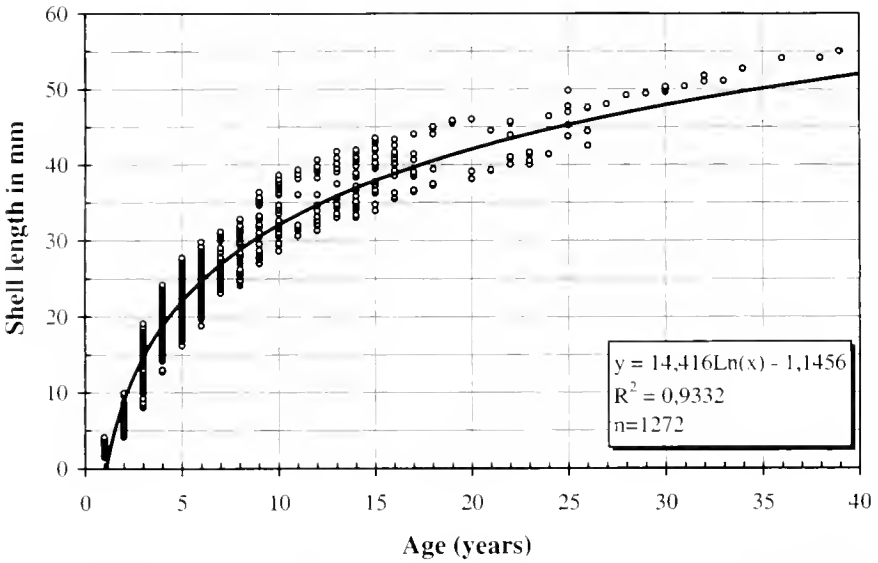

Figure 10. Growth curve of *Arctica islandica* from the Mecklenburg Bight for the first 40 years of life.

the growth rates of a Kiel Bay population calculated by Brey et al. (1990), the growth in the Mecklenburg Bight was slower. *A. islandica* in the Kiel Bay reached about 84 mm after 40 years; whereas, the specimens in the Mecklenburg Bight had a mean shell length of 52 mm in the same time. These differences are difficult to explain. The lower salinity may be one reason for the observed slower growth of quahogs in the Mecklenburg Bight. A possible further explanation might be that the Kiel Bay higher bottom currents (closer openings to the Small and Great Belt), enriched in suspended or re-suspended material, would supplement *A. islandica*, as a filter-feeder, with advective food supply (see Witbaard et al. 1999).

The present study shows the peculiarities of the ocean quahog in the Mecklenburg Bight near its eastern distributional boundary within the Baltic Sea. Further investigations must deal with the differences in observed growth rates of quahogs within the Baltic and adjacent waters. The comparative population dynamics of different water depths and/or sediment structure and the dispersion and settlement patterns of the larvae in this "border" area are of interest. Two of the main questions following this study are: Is the short life expectancy of quahogs in the Baltic due only to the salinity and which conditions cause the success of strong recruitment in its geographical distribution.

ACKNOWLEDGMENTS

Parts of this work were supported by the German Umweltbundesamt and the Bundesministerium für Forschung und Technologie. The authors are indebted to Volker Schroeren (LANU Schleswig-Holstein) and to Dr Heye Rumohr (IfM Kiel) for supplying of data. We would like to thank Dr Herbert Siegel and Monika Gerth for introducing into the Surfer program. Thanks are also to Christine Peters and Toralf Hoth for helpful technical assistance.

GROWTH, SURVIVORSHIP, AND NUTRIENT UPTAKE OF GIANT CLAMS (*TRIDACNA*) IN AQUACULTURE EFFLUENT

MARIA SPARSIS,[1,2] JUNDA LIN,[1,*] AND RANDOLPH W. HAGOOD[2]

[1]*Department of Biological Sciences, Florida Institute of Technology, Melbourne, Florida 32901;*
[2]*Proteus Consulting Inc., Vero Beach, Florida*

ABSTRACT Experiments were conducted to evaluate the feasibility of using juvenile giant clams (*Tridacna*) to remove dissolved inorganic nutrients (nitrate and phosphate) from aquaculture effluent. Three (*T. derasa* Roding, *T. maxima* Roding, and *T. squamosa* Lamarck) of the four species tested during a two-month experiment all had very high survivorship in both effluent and control seawater, but *T. gigas* (Linne) experienced 50% mortality. *T. maxima* and *T. squamosa* showed virtually no growth in both effluent and control waters. *T. gigas* had the fastest growth rate among the four species. *T. derasa* grew significantly faster in effluent than in seawater. In a 24-h experiment (12 h dark followed by 12 h light), all the four species absorbed similar and significant amounts of nitrate and phosphate from effluent during the light period. Our study demonstrates that although it may not be possible to rely on giant clams alone to remove all excess dissolved nutrients from intensive food fish aquaculture effluent, it is entirely feasible to use giant clams to remove all excess nutrients in effluent of marine ornamental species. Giant clams can be either incorporated into a polyculture system with other marine aquarium trade species, or they can be grown in effluent in separate tanks.

KEY WORDS: aquaculture effluent, giant clams, growth, juvenile, nutrient uptake, survivorship, *Tridacna*

INTRODUCTION

In recent years, environmental impact and sustainable development have been central issues for aquaculture (e.g., Chua 1992, Pillay 1992, Shpigel et al. 1993, Shpigel & Neori, 1996). Many solutions have been attempted to remove the particulate and/or dissolved nutrients in aquaculture effluent. One way of alleviating aquaculture's environmental impact is to utilize recirculating system technology, thus reducing the amount of effluent introduced into the environment and allowing facilities to be located inland. Water exchange is most commonly used to prevent nutrient build-up in a recirculating system. The obvious drawback to this technique is the production of effluent, which must be disposed of under permitting restrictions. To completely eliminate effluent discharge, water from recirculating systems must be treated to remove particulate and dissolved waste before reintroduction to the culture system.

One of the techniques employed to treat effluent is to utilize micro- and macro-algal primary production to take up dissolved nutrients (e.g. Subandar et al. 1993). Suspended solids are usually removed by mechanical filtration. Biofiltration by bivalve mollusks has also been used to remove particulate waste from aquacultural effluent. In China, there is a long tradition of using polyculture and integrated culture to produce additional crops and reduce negative impacts on the environment (Yang et al. 1992). Integration of bivalve and/or seaweed culture to remove suspended particles and/or dissolved nutrients from aquaculture effluent has also been shown to be effective (e.g. Jones & Iwama, 1991, Shpigel et al. 1993).

Giant clams (family Tridacnidae) are unique among bivalve mollusks in that they possess symbiotic algae (*Symbiodinium microariaticum*) in their mantle tissue. In contrast to reef-building corals, the giant clams cultivate the symbiotic zooxanthellae in a special tubular system (Norton et al. 1992) which enables them to keep a substantially higher number of symbionts per unit area (Knop 1996). These algae contribute a variety of photosynthetically produced compounds to the host's metabolic needs (Lucas 1988). The single-cell thick tubes are bathed in haemolymph, allowing the efficient supply of nutrients to and photosynthate from the zooxanthellae (Belda & Yellowlees 1995). Klumpp et al. (1992) describe the tridacnids as "trophically opportunistic," capable of deriving nutrition using autotrophic or heterotrophic means.

Giant clams are endemic to the Indo-Pacific waters. The nine described species, *Hippopus hippopus* Linne, *H. porcellanus* Rosewater, *Tridacna crocea* Lamarck, *T. derasa*, *T. gigas*, *T. maxima*, *T. rosewateri* Sirenko and Scarlato, *T. squamosa*, and *T. tevoroa* Lucas, Ledua, and Braley, range from 10 cm to over 1 m in shell length (SL) as adults (Lucas 1988, Lucas et al. 1991, Knop 1996). They have formed a significant part of human diets in the Indo-Pacific and Southeast Asia for thousands of years. Clamshells have also been marketed. In recent years, giant clams have been successfully farmed for food, for restocking over-fished tropical reefs and, more recently, for the aquarium trade. The juvenile clams are popular in the aquarium trade due to their brightly colored mantle tissue, which is often exposed to allow light entry for algal photosynthesis. Their retail price ranged from $20 to over $200 per animal in the US. The brownish background coloration of the mantle is caused by the zooxanthellae, but the iridescent pigmentation creating different patterns in a variety of colors is not due to the algae (Knop 1996). This bright pigmentation may protect the clams against UV light or too much light in general and confuse potential predators (Knop 1996).

Tridacnids are ideal candidates for treating mariculture effluent. They have been successfully reared in captivity and are fast growing, reaching the 8–10 cm SL aquarium market size in only 2–3 years. Because of their unique trophic style, they could be successfully incorporated into recirculating mariculture systems to remove both nutrient and particulate waste. In addition, tridacnids are popular as aquarium pets and in the sushi/sashimi markets and would therefore be a valuable by-product.

We conducted a series of experiments to evaluate the potential of using the tridacnids for tertiary effluent treatment. The growth, survivorship, and nutrient uptake rate of four giant clam species growing in aquaculture effluent were compared.

MATERIALS AND METHODS

Growth and Survivorship

In November 1996, juveniles of four giant clam species, *T. derasa*, *T. gigas*, *T. maxima* and *T. squamosa*, were obtained from a local aquarium dealer. The sizes were similar within a species, but considerably different among the species (Table 1), as constrained by the availability. The clams were imported from the Solomon Islands where they were farm-raised.

Upon arrival, the clams were acclimated to filtered seawater over a period of one hour. Clamshells were brushed briskly under running fresh water to remove any epiphytes and potential parasites. The clams were then introduced to two indoor raceways (245 cm long and 30 cm wide) filled with 15-cm deep seawater (110 L). Two metal halide lamps, 60 cm above the raceways, were used to provide sufficient light intensity and appropriate wavelength composition (Knop 1996). The light intensity maintained at 350–400 $\mu E/s/m^2$ and photoperiod was set at 12 hours light and 12 hours dark. The water temperature was maintained at 25–29°C, salinity at 35 ppt, and pH at 8.3, within the range for optimal growth for the giant clams (Lucas 1988, Price & Fagolimul 1988, Knop 1996).

After one week the clams were removed from the system, measured (SL) and tagged. The 48 clams were then randomly divided into the two raceways again (24 clams, six for each of the four species, in both the control and treatment raceways). For the following two months, 10% of the water in the raceways was replaced daily. In the control raceway, water was replaced with fresh filtered seawater; while the treatment raceway received effluent water from a fin fish aquaculture facility. Dissolved nutrient concentrations of the added effluent varied and were tested weekly, as were those of the filtered seawater, control and treatment raceways.

In the course of the two-month study period, biofouling became a problem, particularly in the treatment raceway. Two different species of parasitic snails were also found preying on the clams. *Cymatium muricium* feeds on the mantle of clams and the parasitic pyramidellid snails feed on clams' lymphatic fluid (Knop 1996, Boglio & Lucas 1997). To mitigate these problems, the clams were periodically removed from the raceways and brushed under running freshwater and returned to the raceways. Since most of the biofouling appeared to be algae, 25 herbivorous gastropods (*Astrea tecta*) were added to each raceway to control algal growth. Both techniques proved to be very effective. After two months of monitoring, all the clams were again removed from the raceways and measured (SL).

Dissolved Nutrient Uptake

A separate experiment was conducted to compare the dissolved nutrient uptake rates among the four species in January 1997. All the clams used in the experiment had been acclimated to effluent water for at least two weeks prior to the study. Only healthy looking clams with quick shell closing responses were used.

Each clam was immersed in a 500-ml beaker with 1-μm filtered effluent water of known nutrient concentrations of dissolved nitrate (NO_3) and phosphate (PO_4). Five replicate clams were used for each species. Again, the sizes were similar within a species, but considerably different among the species. Mean (±s.d.) SL for *T. derasa*, *T. gigas*, *T. maxima*, and *T. squamosa* are 60.2 (±2.2), 84.8 (±5.4), 32.4 (±1.7) and 36.6 (±2.3) mm, respectively. Two controls (each with a pair of empty giant clamshells) were set up. Nitrite and ammonia levels in the effluent were below detection limit (0.01 ppm) at the beginning and end of the experiment. The clams remained in darkness for 12 hours after which a sample of the effluent was removed from each beaker and tested for nitrate and phosphate concentrations. The clams remained immersed for an additional 12 hours under light with intensity of 350–400 $\mu E/s/m^2$. Samples of the effluent were again removed and tested during the 12-hour light period (every two hours for nitrate, at the end of the 12-hour light period for phosphate). The water temperature was maintained at 2–29°C, salinity at 35 ppt, and pH at 8.3.

Measurement of dissolved nutrient (ammonia, nitrite, nitrate, and phosphate) concentrations followed the techniques described in Menzel and Corwin (1965), D'Elia et al. (1975), and Greenberg et al. (1985). Ammonia was determined using the direct nesslerization method, nitrate the cadmium reduction method, nitrite the azo-dye formation technique, phosphate the persulfate oxidation method and the resulting orthophosphate be measured using the ascorbic acid method. Color development in all cases was measured using a spectrophotometer.

RESULTS

Growth and Survivorship

All the individuals of *T. maxima* and *T. squamosa* survived. One *T. derasa* in the treatment tank and three (50%) *T. gigas* in both treatment and control tanks died. *T. derasa* and *T. gigas* displayed some growth during the study, whereas *T. maxima* and *T. squamosa* showed virtually no growth (Table 1). Only *T. derasa* showed significant difference in growth ($P = 0.008$, *t*-test) between the treatment and control tanks (Table 1).

Concentrations of dissolved nutrients in the seawater and control tanks remained low (Fig. 1). Except for the first two weeks, concentrations of ammonia and nitrite in the effluent and treatment tanks were also low (Fig. 1), probably due to the nitrification process carried out by the biofilter in the fin fish culture facility. The concentrations of nitrate (Fig. 1c) and phosphate (Fig. 1d) in the treatment tanks were lower than those in the effluent tanks, suggesting that the clams were removing the nutrients throughout the two-month period.

TABLE 1.

Mean (±s.d.) initial SL and SL increase of the four clam species after the two months of immersion in control (C) and treatment (T) raceways.

	T. derasa		*T. gigas*		*T. maxima*		*T. squamosa*	
	C (n = 6)	T (n = 5)	C (n = 3)	T (n = 3)	C (n = 6)	T (n = 5)	C (n = 6)	T (n = 6)
Initial SL (mm)	53.8 ± 11.0	59.2 ± 1.6	86.0 ± 6.1	86.7 ± 7.5	33.2 ± 7.5	32.3 ± 1.9	35.6 ± 2.9	36.0 ± 3.0
SL Increase (mm)	0.2 ± 0.4	1.8 ± 1.1	1.3 ± 2.3	2.7 ± 2.1	0.2 ± 0.4	0.0 ± 0.0	0.0 ± 0.0	0.2 ± 0.4

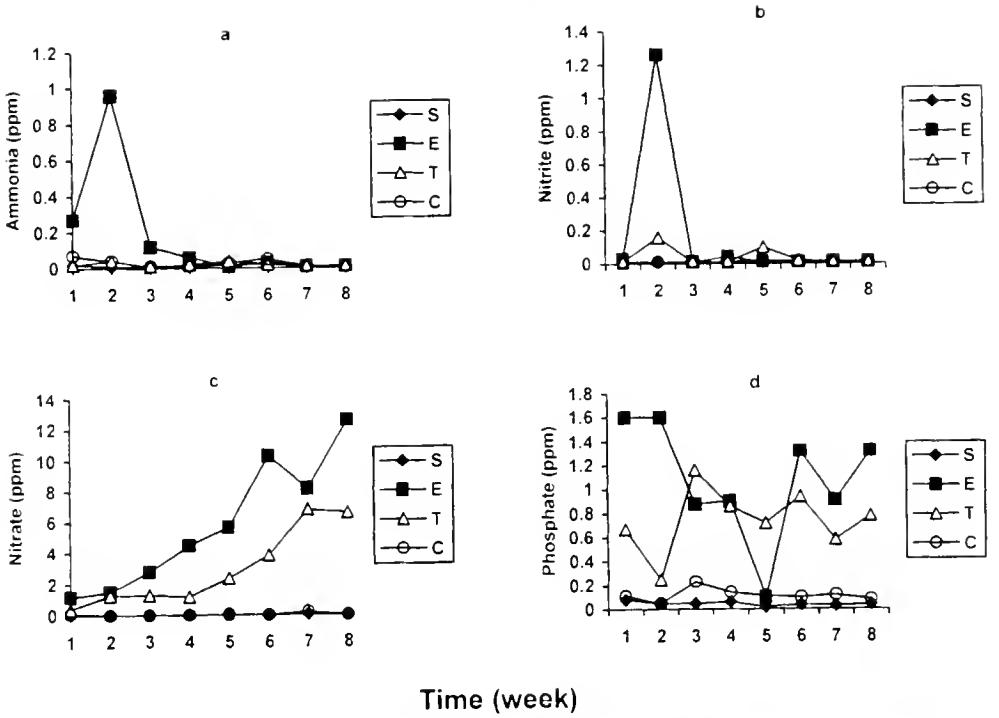

Figure 1. Concentrations of ammonia (a), nitrite (b), nitrate (c), and phosphate (d) in filtered seawater (S), effluent (E), treatment water (T), and control water (C) over the two-month study period.

Dissolved Nutrient Uptake

The concentrations of nitrate and phosphate did not change in the two controls over the 24-h period and in the treatments over the 12-h dark period (Fig. 2). All four species showed rapid uptake of both nitrate and phosphate during the 12-h light period (Fig. 2). Over the 24-h period, the nitrate concentration decreased from 12.6 ppm to an average (±s.d.) of 9.0 (±0.3) ppm for *T. derasa*, 8.0 (±0.2) ppm for *T. gigas*, 10.0 (±0.2) ppm for *T. maxima*, and 9.9 (±0.7) for *T. squamosa* (Fig. 2). Taking clam size into consideration, all four species had similar rates of nitrate uptake. The phosphate concentration decreased from 0.23 ppm to an average (±s.d.) of 0.15 (±0.01) ppm for *T. derasa*, 0.14 (±0.01) ppm for *T. gigas*, 0.14 (±0.00) ppm for *T. maxima*, and 0.18 (±0.00) for *T. squamosa* (Fig. 2). Phosphate uptake rates were also proportional to clam size, except that *T. maxima* seems to be more efficient.

DISCUSSION

Klumpp et al. (1992) describe the tridacnids as "trophically opportunistic," capable of deriving nutrition using autotrophic and/or heterotrophic means. The ability of the giant clams to assimilate inorganic nutrients via photosynthesis has been well-documented (Wilkerson & Trench 1986, Fitt 1988, Mingoa 1988, Solis et al. 1988, Braley et al. 1992, Hastie et al. 1992, Klumpp et al. 1992, Belda et al. 1993b, Fitt et al. 1993, Klumpp & Griffiths 1994, Klumpp & Lucas 1994, Hawkins & Klumpp 1995). Autotrophy under high light intensities may be able to satisfy the basic nutritional needs of the clams (Griffiths & Streamer 1988, Klumpp et al. 1992, Klumpp & Griffiths 1994, Klumpp & Lucas 1994).

Increased growth in the giant clams with increasing dissolved nitrogen concentrations was reported in several studies (Wilkerson & Trench 1986, Solis et al. 1988, Braley et al. 1992, Hastie et al.

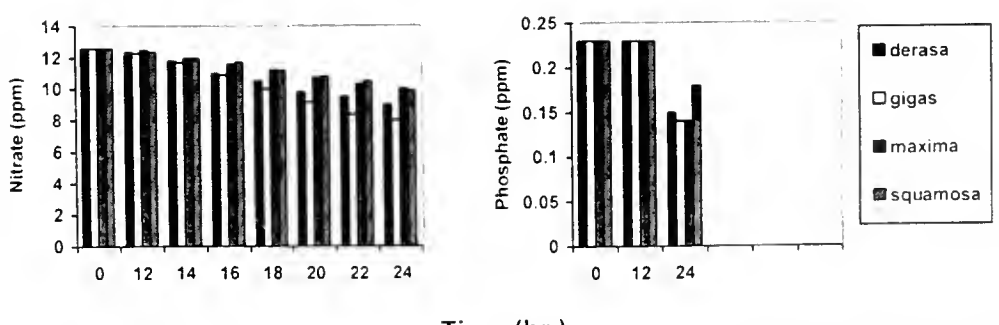

Figure 2. Mean nitrate and phosphate concentrations (ppm) over the 24-h period (12 h dark followed by 12 h light) for *T. derasa* (mean ± s.d. SL = 60.2 ± 2.2 mm), *T. gigas* (mean ± s.d. SL = 84.5 ± 5.4 mm), *T. maxima* (mean ± s.d. SL = 32.4 ± 1.7 mm), and *T. squamosa* (mean ± s.d. SL = 36.6 ± 2.3 mm).

1992, Fitt et al. 1993). In a 60-day nutrient enhancement study with *T. derasa* (Hastie et al. 1992), the clams grown in elevated dissolved inorganic nitrogen had both higher SL and tissue weight increments over untreated controls. Ammonium and nitrate were equally effective and no detrimental physiological effects of enrichment were detected. The clams (initial average size: 27.6 mm SL) in the elevated nitrate treatment grew an average of 0.1–0.16 mm SL/day, as compared to 0.06 mm SL/day for the control seawater (Hastie et al. 1992). In our two-month study, the much larger sized (average initial SL were 53.8 and 59.2 mm for control and effluent tanks, respectively) *T. derasa* grew an average of 0.03 mm SL/day in the effluent, but had negligible growth (0.004 mm SL/day) in the control seawater. A large-scale grow-out study at 11 village farms in Solomon Islands (Hart et al. 1998) found that among the juveniles (20–30 mm SL) of giant clam species tested, *T. derasa* had the best growth (0.14 to 0.21 mm SL/day) and survival (80.1 to 99.1%), and therefore the highest estimated revenue for the aquarium trade, than those of the other two species tested: *T. maxima* (growth: 0.07–0.14 mm SL/day, survivorship: 16.0–72.7%) and *T. crocea* (growth: 0.04–0.07 mm SL/day, survivorship: 11.8–81.9%). In a similar 8-month grow-out study on *T. squamosa* in the Solomon Islands (Foyle et al. 1997), the clams (initial size about 24 mm SL) grew an average of 0.08–0.29 mm SL/day with the survivorship ranged from 7–83%. Growth rates of juvenile *T. squamosa* found in other studies ranged from 0.05–0.23 mm SL/day (Klumpp & Griffiths 1994, Foyle et al. 1997). *T. gigas* has the highest growth rate (0.13–0.37 mm SL/day) among the giant clam species tested in our experiment and other studies (see Table 7 of Klumpp & Griffiths 1994 for a review summary). The average daily growth rates of *T. gigas* in the control seawater (0.02 mm SL) and in effluent (0.05 mm SL/day) in our study are much lower than those of the other studies. Interestingly, while effluent greatly enhanced the growth of *T. derasa* and probably *T. gigas*, it did not have an effect on the other two species: *T. maxima* and *T. squamosa*. In fact, these two species showed virtually no growth during the two-month period, in effluent as well as in control seawater (Table 1).

Giant clams are hardy animals and have excellent survivorship when grown in effluent in a recirculating system. Among the four species tested in both seawater and effluent in our two-month study, *T. gigas* was the only species that suffered significant (50%) mortality. However, available literature does not indicate that *T. gigas* is less hardy than the other species. Ranellids (e.g., several species of *Cymatium*) and pyramidellid snails are common predators/parasites of tridacnid clams in the wild and can cause serious mortality (Knop 1996, Boglio & Lucas 1997). The pyramidellid snails are obligate parasites with various degrees of host specificity. They use their proboscis to penetrate the hosts and gain their nutrition by feeding purely on the hosts' body fluid (Boglio and Lucas, 1997). The snails are small (a few mm) nocturnal feeders and can be difficult to detect and remove. Therefore, it is critical to carefully examine imported clams for parasites.

The four species tested in our study showed similar capabilities of absorbing both nitrate and phosphate, after taking clam size into consideration. The nitrate uptake rates found in our study are similar to those found in the studies of juvenile *T. derasa* grown on seawater spiked with artificial nutrients (Hastie et al. 1992, Fitt et al. 1993). Fitt et al. (1993) also found that the rate of NO_3 uptake was lower than that of NH_3. In fact, uptake of NO_3 was repressed in the presence of NH_3. In the present study, low NH_3 concentration in the effluent may have facilitated the uptake rate of nitrate by the clams. In the study of Fitt et al. (1993), no detectable uptake of ammonia and much lower uptake rate of nitrate in the dark as compared to under light were found. Among the four clam species we tested, virtually no uptake of nitrate or phosphate took place during the 12-h dark period (Fig. 2).

There has been limited study of phosphate uptake by giant clams. Large juvenile *T. gigas* (22–26 cm in SL) can take up significant amount of phosphate, with the individuals previously held in control seawater deplete phosphate at a much greater rate (11.5 μM P/hr.) than the ones previously held in phosphate-supplemented (10 μM) raceways (4.3 μM P/h) (Belda & Yellowlees 1995). The four species we tested, especially *T. maxima*, can rapidly absorb phosphate from seawater in the light period (Fig. 2). They are also capable of continuously removing phosphate for an extended period of time (Fig. 1d). Zooxanthellae do not have ready access to inorganic phosphate in seawater and within the clam (Belda et al. 1993b, Belda & Yellowlees 1995). The clam host may actively regulate P availability to its symbiotic algae (Belda et al. 1993b). Juveniles of *T. derasa* exposed to elevated phosphate (2 μM) alone actually grew less than control clams and phosphate additions to elevated dissolved inorganic nitrogen treatments had little apparent effect on the clam's growth rates (Fitt et al. 1993). High concentrations of phosphate inhibit calcification (Simkiss 1964) and may have a negative effect on the growth of giant clams. Further studies are needed to examine the effects of dissolved phosphate concentration on clam's growth if aquaculture effluent is to be used for culturing giant clams.

Elevated nutrients of inorganic nitrogen and phosphorus, however, may lead to weakening shell structure in the giant clams, resulting in thinner and more transparent shells (Belda et al. 1993a). Ammonium, as well as phosphate, may inhibit or depress calcification in clams (Simkiss 1964, Belda et al. 1993b). These clams may be more vulnerable to predation if released to the wild, but would not have any negative impacts when used in the aquarium trade. Enhanced nutrients also increase biofouling in the clams, but this can be removed by gentle scrubbing with a toothbrush (Hastie et al. 1992; present study) or by introducing appropriate grazers, such as herbivorous snails (present study).

The relative importance of autotrophy in giant clam nutrition has been the subject of speculation for many years (Trench et al. 1981, Fisher et al. 1985). The relative contributions of phototrophy and heterotrophy toward the carbon requirements vary among the tridacnid species and among different sized clams within a species (Klumpp et al. 1992, Klumpp & Griffiths 1994, Klumpp & Lucas 1994). *T. gigas* was the most efficient in uptake of C via both photosynthesis and filter feeding among the four species compared (*T. gigas*, *T. crocea*, *T. squamosa*, and *Hippopus hippopus*). The interspecific differences, however, declined with clam size (Klumpp & Griffiths 1994). Filter feeding is able to provide over half of the total carbon needed both for respiration and growth in small individuals of *T. gigas* (Klumpp et al. 1992). However, filter feeding is a relatively minor source of energy in other species (*T. crocea*, *T. derasa*, *T. squamosa*, *T. tevoroa*, and *Hippopus hippopus*) and its importance decreased with increasing clam size (Klumpp & Griffiths 1994, Klumpp & Lucas 1994). In the present study, the degree of nutritional contribution to the clams by small particles in the effluent is unknown.

Among the four species we tested, *T. derasa* is probably the best candidate for culturing in aquaculture effluent. In addition to growth, survivorship, and nutrient uptake parameters, seed availability and ease of cleaning to remove epiphytes and parasites also

need to be taken into consideration. All the four species are equally susceptible to epiphyte infestation, but those with smooth shells, such as *T. gigas* and *T. derasa*, are easier to clean by scrubbing. The highly fluted shells of *T. squamosa* and *T. maxima* are more likely to harbor parasites and other epifauna, which are harder to detect and remove due to the shell's high relief. Seed of *T. gigas* is becoming difficult to obtain as most hatcheries are concentrating on the more colorful species. All the four species are popular in the aquarium trade, with the more colorful *T. maxima* commanding higher prices.

It may not be possible to rely on giant clams alone to remove all the dissolved nutrients from intensive food fish aquaculture effluent at a commercial scale. However, it is entirely feasible to use giant clams to treat aquaculture effluent of other marine ornamental species. Most of more than 3,000 species of marine fishes and invertebrates marketed in the aquarium trade industry in the world are collected from coral reef systems. Concerns over the impacts of wild harvest, with expanding popularity of coral reef animals in the aquarium trade, have spurred interest in developing or improving cultivation technology for marine ornamental fish (Fletcher et al. 1999, Holt 1999), shrimp (see Lin et al. 1999 for a review), corals (Carlson 1999), giant clams, and other invertebrates.

Either giant clams can be incorporated into the other aquarium species in a polyculture system, if the environmental requirements are compatible between (among) the species; or they can be grown in effluent in separate tanks. The clams can be grown not only in tropical and subtropical regions, but also in greenhouses in temperate areas, as currently practiced by the aquarium industry. In colder areas and/or months, the effluent may be diverted to an indoor greenhouse to be treated by the giant clams (Braley et al. 1992). Growing juvenile giant clams in recirculated water would also pave the way for inland culture (Braley et al. 1992), thereby eliminating the possible negative consequence of introducing exotic species.

ACKNOWLEDGMENTS

Financial support was jointly provided by the Sea Grant (Grant number: NA36RG-0070) and the Atlantic Aquaculture Technologies, Inc. Butch Almberg of Reef Rascal Aquarium provided clams and advice. Dick Perrin of Tropicorium provided valuable technical advice. Mary Clark and LeRoy Creswell of Harbor Branch Oceanographic Institution shared their clam references. The late Dr. Kerry Clark of Florida Institute of Technology helped in formulating the initial concept of the project. Steve Arneson, Jeremy Baker, Morris Bevis, Amy Riedle, Tiffany Williamson, and Harry Yamalis provide various assistance during the study. Dong Zhang produced the figures. Helpful comments were provided by anonymous reviewers.

REPRODUCTIVE CYCLE AND BIOCHEMICAL COMPOSITION OF THE ARK SHELL *SCAPHARCA BROUGHTONII* (SCHRENCK) IN A SOUTHERN COASTAL BAY OF KOREA

MI SEON PARK,* CHANG-KEUN KANG, AND PIL-YONG LEE

National Fisheries Research & Development Institute, Shirang Kijang-Gun, 619-900 Pusan, Republic of Korea

ABSTRACT The reproductive cycle and biochemical composition of the ark shell *Scapharca broughtonii* (Schrenck) in Chinju Bay, a southern coastal bay of Korea, were studied from July 1999 to August 2000 in relation to environmental conditions (temperature, salinity and available food). Animals were cultured in the bottom. *S. broughtonii* from Chinju Bay was characterized by a spawning period during July to September due to a monocyclic gametogenesis throughout the year. Clear seasonal cycles in biochemical composition of the animal tissues were recorded. Summer spawning of *S. broughtonii* was followed by a clear accumulation period of reserve materials in autumn (from October to December). A great increase in animal tissue weight was attributed to the rapid accumulation of protein and carbohydrate during that period. A new cycle of gametogenesis began at the lowest water temperature in February. The gonadal growth during winter to spring when the available food was poor took place at the expense of reserves (mainly glycogen) accumulated previously in autumn. Lipid biosynthesis during gametogenesis was associated with glycogen breakdown. Blooms of phytoplankton in the ambient waters took place in the low saline summer period when water temperature was highest, depending on the addition of excessive nutrients via streams. Spawning of *S. broughtonii* occurred at the time when the available food was very abundant. This seemed to enable larvae to be produced at the most opportune moment with regard to food availability, as previously proposed. Our results indicate that this bivalve may be considered a typical conservative species in gametogenic pattern.

KEY WORDS: *Scapharca broughtonii*, reproductive cycle, bivalves, biochemical composition, seston, food index

INTRODUCTION

The southern coastal bay systems in Korea have been widely exploited for shellfish cultures. In the shallow semi-enclosed coastal bays, uncontrolled increases in stock density often result in reduced growth rates and environmental disruption thereby causing mass mortality of cultured bivalves (Park et al. 1998, Park et al. 1999). The ark shell *Scapharca broughtonii* (Schrenck) is cultured in the bottom of the inshore bay systems. Thus, this shell, which is a common benthic suspension feeder from intertidal to subtidal zone along the northwestern Pacific coast, is one of the most important commercial bivalve species in Korea. Morphological and genetic differences between the ark shell populations of Korea, China and Japan have been found (Lee et al. 1997, Yokogawa 1997). Annual production of the ark shell *S. broughtonii* in Korea was maximized in 58,000 tonnes in 1986. However, since the 1990s production has decreased, depending largely on local shortages of healthy seed (Rho & Pyen 1977, Park et al. 1998). Knowledge of reproductive strategy in a given area could have essential importance for collecting ark shell seed from nature.

Up to now, biological studies on the ark shell have been limited to natural and artificial seed collection and growth of spat (Kim & Koo 1973, Yoo & Yoo 1974, Pyon et al. 1976, Rho & Pyen 1977, Kim et al. 1979, Kim & Yoon 1980). Little attention has been paid to the physiological ecology and gametogenic cycle (Park et al. 1998). The reproductive cycles of marine bivalves are strongly related to energy storage-utilization cycles and environmental parameters such as water temperature and food availability (Giese 1969, Gabbott 1975, 1983, Bayne 1976). Therefore, seasonal cycle and frequency of the reproductive activity in marine bivalves exhibit geographical variations within a single species (Bayne & Worrall 1980, Newell et al. 1982, Rodhouse et al. 1984, Bricelj et al. 1987). Gametogenesis is an energy-demanding process. The use of energy required for gametogenesis differs between species. According to the classification of Bayne (1976), one group, called opportunistic species, uses the recently ingested energy from seston and another group, conservative species, uses the energy stored in various organs through feeding prior to its gametogenesis. The seasonal cycles of gametogenesis and reserve storage in *S. broughtonii* may reveal its reproductive strategy in relation to local environmental conditions.

This study presents the reproductive cycle and biochemical composition of *S. broughtonii* cultured in the bottom of Chinju Bay, a southern coastal bay system of Korea. The objective of the study was to observe the seasonal cycles of energy storage-consumption in the ark shell, to examine the use of reserve materials in relation to the gametogenic cycle and the environmental parameters, and to establish the gametogenic pattern.

MATERIALS AND METHODS

Study Site

Chinju Bay is a small shallow bay system (average depth 4 m) situated on the southern coast of Korea (Fig. 1). It is well protected by Namhae and Changsun Islands to the south. The bay is about 25 km long and 13 km wide. It is a well-mixed bay and the tide is semidiurnal with a maximum tidal range of 3.6 m and strong tidal currents. Freshwater pulses occur irregularly from an artificial dam of the Nam River on the north of the bay. Sediments of the bay are composed mostly of mud. A broad area (about 8 km^2) of its subtidal zone has been developed for bottom culture of the ark shell *S. broughtonii*. The sampling station for the study was located in the southwestern part of the bay. It was 3 m deep at the low tide and 6 m at the high tide.

Sample Collection and Preparation for Analysis

Fifty to 100 specimens of *S. broughtonii* were collected randomly by diving at monthly intervals from June 1999 to August

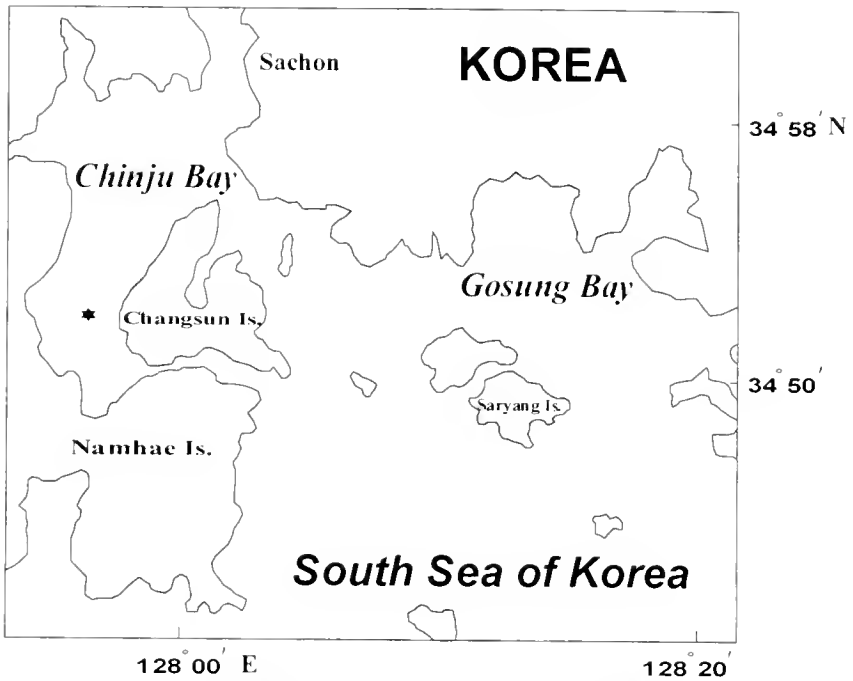

Figure 1. Location of the site for ark shell collection and environmental measurements in Chinju Bay, Korea.

2000. Mean shell length was 66.5 (± 6.2) mm for one-year class. These animals were seeded on the bottom in April 1998. All animals were carried to the laboratory quickly and kept alive overnight to evacuate gut content. After biometric measurements (shell length, width, height, and total weight) they were dissected carefully. The flesh was weighed for wet tissue weight and freeze-dried for the determination of dry tissue weight and biochemical composition. Shell valves were rinsed with distilled water and weighed after drying in a furnace at 50°C for 48 h. Temperature and salinity of the surface and bottom waters were recorded at the time of sampling by a CTD meter (Seabird Electronics, Inc.). We first investigated the characteristics and the seasonal variability of seston of the bay. Waters for seston measurements were pumped for the surface and bottom waters at the same time and screened through a 180-μm Nitex mesh to eliminate zooplankton and large debris. Water samples for suspended particulate matter (SPM) were immediately filtered through a preweighed Whatmann GF/C glass-fiber filter. For pigment and chemical analysis, 0.5 to 3-L aliquots were concentrated on GF/F filters on board *in situ* and the filters were carried to the laboratory. All filters were then kept frozen (−80°C) until analyzed.

Seston Analysis and Food Index

Filters for dry weight were dried at 80°C for 24 h and reweighed after cooling in desiccator. Chlorophyll *a* concentration was determined on acetone extracts using fluorometric method as modified by Parsons et al. (1984) with 10 AU Fluorometer (Turner Designs). Biochemical components of seston (particulate protein, carbohydrate and lipid) were analyzed by the same methods as described later for animal tissues. An evaluation of the nutritional value of the seston throughout the year was done using the biochemical composition. Food quantity was defined as the sum of the concentrations of these components and a food index was calculated as the percentage of food in the seston [(Food/Total Seston) ×100] (Widdows et al. 1979).

Condition Index and Reproductive Activity

Temporal variation of condition index reveals either the onset of accumulation of organic matter for reproduction or release of gametes. The condition of the ark shells was estimated from an index that was expressed as dry tissue weight:dry shell weight (Walne 1976, Mann & Glomb 1978). Thirty individuals from each sample were used for microscopic examination of histological smears. A transverse cut was made across the body of the ark shell and a section 3-mm thick was fixed in Bouin's solution. It was then routinely processed for histology and 5-μm paraffin-imbedded sections were stained with iron hematoxylin-eosin (Humason 1979). The stage of gonadal development was classified and scored on a 0 to 4 scale according to a scale of maturity (Ivell 1979). At grade 1, sexes are just identifiable but very little gonad is developed. Grade 2 represents a stage of moderate gonadal development. At this grade, oocytes are beginning to develop. At grade 3, gonads are distended and ripe. At this stage, gametogenesis is complete but spawning has not yet occurred. Oocytes are liberated freely on dissection and free sperm are manifested as streaks. Grade 4 is the spawning stage of animals and in half-spent to completely spent condition. Grade 0 represents both the completely spent stage and the immature stage. At this grade, sexes are unidentifiable. The arithmetic means of the individual scores of the whole sample was recorded as the Gonadal Maturity Index (GMI) for each sampling date (see details in Dinamani 1987).

Biochemical Measurements of Animal Tissue

The dry tissue of 20 individuals was pooled and homogenized to determine average biochemical composition. Protein was determined by the colorimetric method of Lowry et al. (1951) after extraction with normal sodium hydroxyde. Carbohydrate and glycogen were extracted in 15% trichloroacetic acid, and precipitated with 99% ethanol. They were analyzed using the phenol-sulfuric acid method as described by Dubois et al. (1956). Extraction for

total lipid was performed in a mixture of chloroform and methanol (Bligh & Dyer 1959) and lipid content was determined using the method of Marsh and Weinstein (1966). Ash content was obtained by igniting a subsample (30 to 80 mg) of homogenized tissue at 450 C for 48 h in a muffle furnace.

Standard Animal

To evaluate the physiological state of *S. broughtonii* independent of growth, absolute values for tissue weight and biochemical composition of a standard animal of 66.5 mm in shell length were compared for each sampling date. Allometric equations of $\log_{10}$ dry tissue weight against $\log_{10}$ shell length at each sampling date were determined by linear regression analysis. The results of the biochemical analysis were then expressed in milligrams per standard animal. All regressions were statistically significant ($p < 0.01$). A similar method has been used in the studies for the barnacles, *Balanus balanoides* and *B. balnus* (Barnes et al. 1963), and for the tellin, *Tellina tenuis* (Ansell & Trevallion 1967).

RESULTS

Environmental Parameters

Water temperature increased from March to August and decreased from September to February (Fig. 2). The maximum water temperature was in August 2000 (25.8 C) and the minimum in February 2000 (5.3°C). Salinity was generally variable and lower than 30 psu in summer (June to September), and constant and higher than 30 psu in the other period. The maximum salinity was recorded from January to June 2000 (around 33.6 psu) and the minimum in September 1999 (26.7 psu).

Available Food

Seasonal variations in the concentration and composition of SPM in the water column are presented in Figure 3. SPM concentration recorded several peaks throughout the year (Fig. 3a). The concentration of chlorophyll *a* exhibited a clear seasonal pattern characterized by a marked peak in summer when salinity was very low (Fig. 3b). The peak in 1999 was higher (7.5 $\mu g \cdot l^{-1}$) than in 2000 (around 4.0 $\mu g \cdot l^{-1}$), but the former was recorded in September and the latter was during the June to August period. During the rest of the year, the chlorophyll *a* concentration was relatively low. The food material present in SPM, as represented by the sum of protein, carbohydrate and lipid concentrations, showed a marked summer peak (over 400 $\mu g \cdot L^{-1}$) during the phytoplankton bloom of each year, although another peak was recorded in February 2000 (Fig. 3c). Peak values of the food index, calculated as a percentage of the SPM, were related to the phytoplankton bloom (Fig. 3d). Peak value of ca. 4% was also recorded in winter months December 1999 to February 2000. During the last of the year, the food index decreased to values lower than 2%.

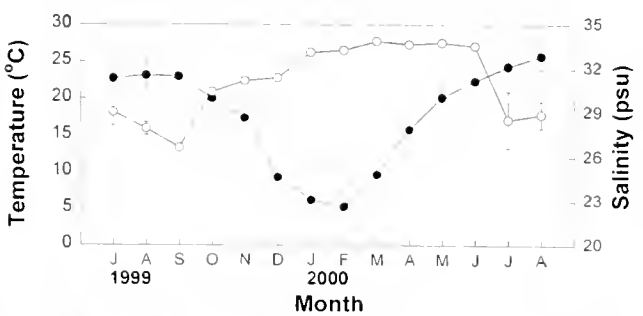

Figure 2. Monthly variations of water temperature (black circles) and salinity (white circles) in Chinju Bay.

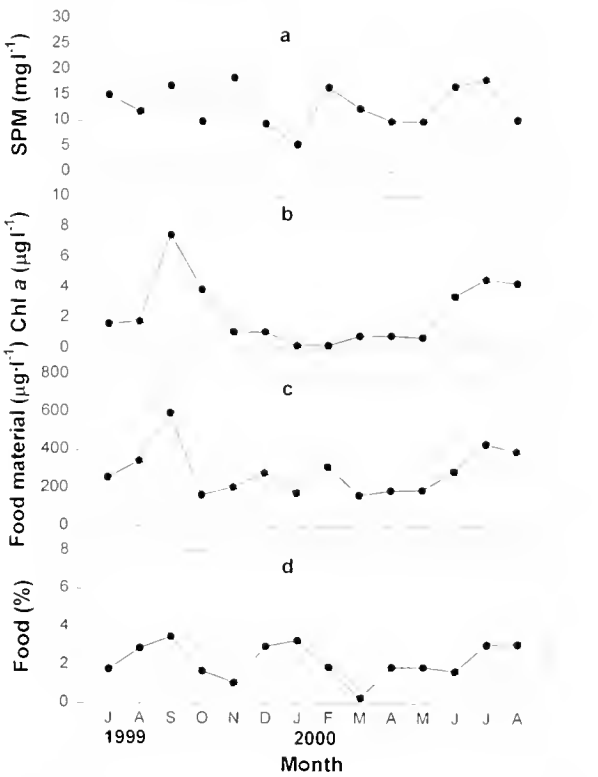

Figure 3. Monthly variations of suspended particulate matter (SPM) (a), chlorophyll *a* (Chl *a*) (b), food material (a sum of particulate protein, carbohydrate and lipid) (c) and food index [(Food material/SPM) × 100] (d).

Condition and Reproductive Cycle

The reproductive cycle of *S. broyghtnii* is characterized by a clear seasonal pattern, as summarized in Figure 4. Maximum values in the condition index were recorded in the early summer months of July 1999 and June 2000, respectively (Fig. 4a). The condition index then decreased sharply to the minimum in late summer of September 1999, suggesting a summer spawning. This index increased progressively from October to June. Since the gametes exhibited the same developmental stage in both female and male follicles, and differences between sexes were not considered in the analysis of biochemical composition, GMI is presented as the means of pooled data from both sexes (Fig. 4b). The development of gonadal tissue started in February and peaked during July to August when the condition index dropped suddenly. Ripe gonads were found from June to August (Fig. 4c). According to the dates of appearance and disappearance of grade 4, which is used as criteria for the beginning and end of spawning, spawning began in July and terminated in September. After spawning, there was a sexual resting period from October to January.

Tissue Weight

Seasonal change in tissue weight for a standard animal (shell length = 66.5 mm) in Chinju Bay is presented in Figure 5. The dry

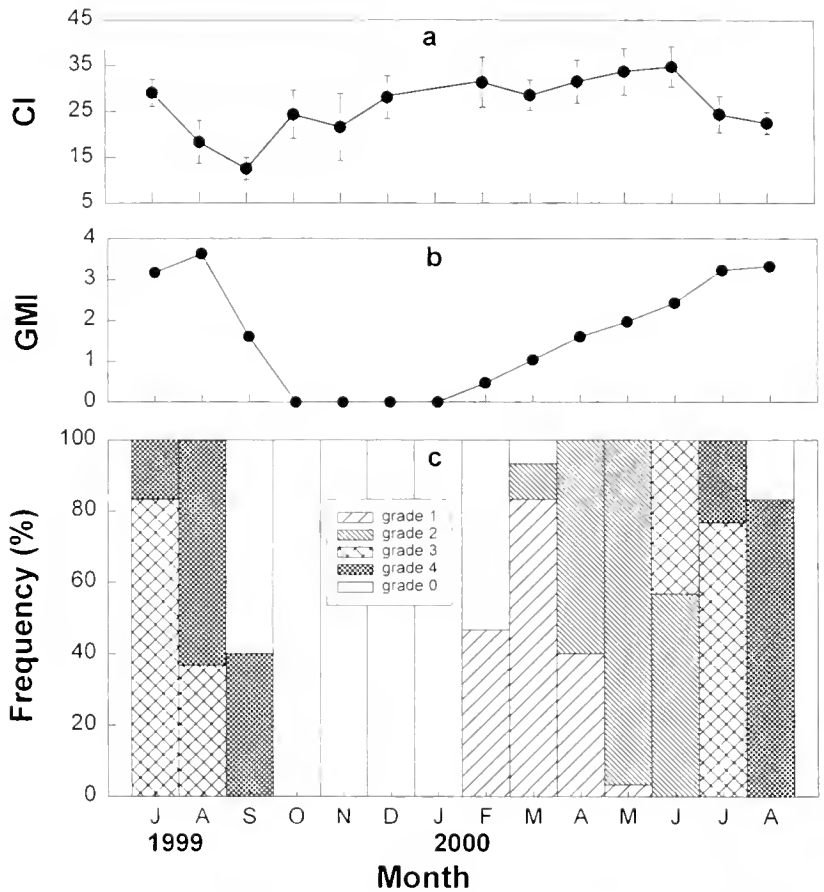

Figure 4. *Scapharca broughtonii.* **Monthly variations of condition (CI) (a), gonad maturity index (GMI) (b) and gonadal development (c).**

tissue weight was maximal in July 1999 and June 2000 (*ca.* 7 mg · standard animal^{-1} for both cases). The tissue weight fell abruptly in summer when spawning occurred. Then, there was a great increase in tissue weight at the timing of sexual resting stage and reserve buildup (see later) during the autumn period (October to December). Thereafter, only a little tissue weight increased steadily during the winter to spring period (February to May).

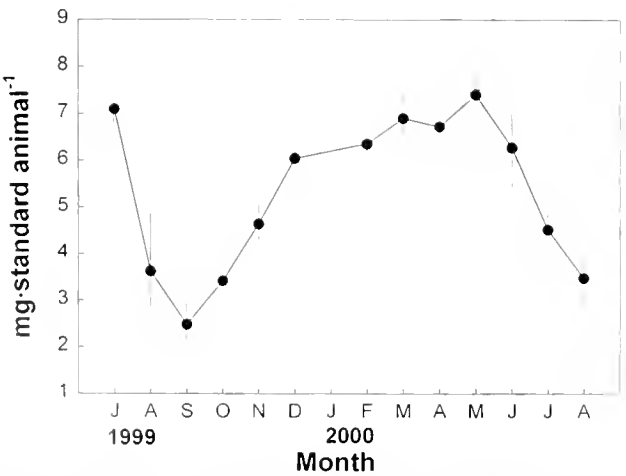

Figure 5. *Scapharca broughtonii.* **Monthly variations of dry tissue weight in a standard animal (shell length = 66.5 mm).**

Gross Biochemical Composition

The gross biochemical composition of a standard animal was calculated from the percentage compositions of each component and the dry tissue weight in Figure 5 and Figure 6 summarizes seasonal cycles of the biochemical components in absolute values as mg dry weight per standard animal. A sudden fall in all the biochemical components of a standard animal occurred during the summer spawning. Thereafter, a great increase in protein and carbohydrate was synchronous with the increase in tissue weight during the autumn period (October to December). At this period, the greater increase in carbohydrate reflected the storage of glycogen reserve in the soft tissue of animals. However, lipid kept lower during this period. During the winter to spring period (February to May), the patterns of variation in each component were different. Protein content continued to increase until May but carbohydrate (also glycogen) content, which was maximal in December, decreased progressively from February to May. Inversely to carbohydrate, lipid content increased steadily during this period. A sharp decrease in all the components was then recorded from June to the end of the study. Ash content showed relatively steady values.

Association between Different Parameters

The Kendall's rank correlation coefficients between the environmental and *Scapharca* measures are presented in Table 1. Chlorophyll *a* concentration was correlated positively ($p < 0.01$) with water temperature but negatively ($p < 0.05$) with salinity, standard

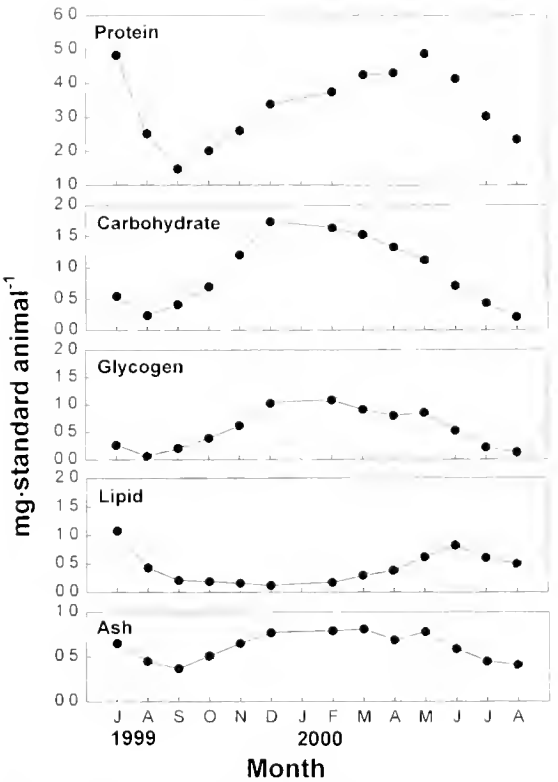

Figure 6. *Scapharca broughtonii*. Monthly variations of biochemical component levels in a standard animal: protein, carbohydrate, glycogen, lipid and ash.

animal protein and carbohydrate (also glycogen) values. Both the condition index and the standard animal dry weight were correlated positively ($p < 0.01$) with its protein value. The GMI correlated positively ($p < 0.01$) with temperature and lipid value but negatively ($p < 0.01$) with carbohydrate (also glycogen) value. With the exception of carbohydrate-glycogen pair, no significant correlation between the absolute values of biochemical components was found.

DISCUSSION

Reproductive Cycle

Changes in temperature, salinity or photoperiod have been considered physical environmental factors, inducing spawning of bivalves (Mann 1979, Dohmen 1985, Lubet et al. 1987). The gametogenesis of *S. broughtonii* in Chinju Bay was characterized by a unimodal cycle, as has been reported for other north Temperate populations of the species in Korea (Park et al. 1998) and Japan coasts (Numaguchi 1996). Positive correlation between GMI and water temperature ($\tau = 0.658$, $p < 0.01$) indicates that temperature might play an important role in inducing the gonadal development and spawning of *S. broughtonii*. A new cycle of gametogenesis began at the lowest water temperature (*ca.* 5.3 C) in February. Similar results were also observed by Park et al. (1998) for other populations of the same species from the southern coast of Korea. However, the lowest water temperature, at which gametogenesis in the latter populations was initiated, was 10°C. This difference indicates that initiation of gametogenesis in *S. broughtonii* occurs at different temperatures in different places, as reported for the oysters *Ostrea edulis* and *Crassostrea gigas* (Ruiz et al. 1992a, b), for the cockle *Cerastoderma edule* (Navarro et al., 1989), for the mussel *Mytilus edulis* (Newell et al. 1982) and for the manila clam *Tapes philippinarum* (Sbrenna and Campioni 1994). In these other species, even spawning also took place at different water temperature. Salinity of Chinju Bay was relatively constant throughout the year with the exception of low salinity in the rainy summer season. No significant correlation between the GMI and salinity was found (Table 1).

Food availability also may have an effect on initiation of spawning. Starr et al. (1990) demonstrated that phytoplankton levels during blooms should be sufficient to induce spawning in sea urchins *Strongylocentrotus drobachiensis* and mussels *M. edulis*. Ruiz et al. (1992a) also postulated that the stimulation by phytoplankton blooms could explain the spawning of *C. gigas* at the low temperature during late October. It is difficult to explicate the summer spawning event by an environmental factor that may trigger spawning. In Chinju Bay, spawning of *S. broughtonii* took place at the moment when water temperature was highest, salinity lowest and photoperiod longest, throughout the year. Also, the blooms of phytoplankton occurred in summer. Kang et al. (1999) reported for the southern coastal bay systems of Korea that the addition of excessive dissolved inorganic nutrients (particularly nitrogen) via streams enhances phytoplankton biomass greatly in the low saline summer period. Therefore, spawning in summer enables larvae to be produced at the most opportune moment with regard to food availability (Newell et al. 1982, see also Navarro et al. 1989).

Numaguchi (1996) observed that spawning of *S. broughtonii* stock cultured in Kasado Bay (Japan) throughout the year took place in insufficient maturation degree from July to September. Spawning of another stock transplanted to Kasado Bay three years after culture in Kagawa Prefecture with the similar latitude and thermal condition was expanded in sufficient maturation from May to October. He concluded that the difference in maturation between two ark shell stocks resulted from nutritive and growth condition. In the present study, the GMI correlated negatively with standard animal carbohydrate and glycogen levels ($\tau = -0.632$ and -0.579, $p < 0.01$ for both). These results indicate that temperature is not the only determinant of gametogenic cycle.

Many authors have taken it into account that nutrient accumulation —depletion cycle in marine bivalves due to variations in ambient food availability may play a critical role in determining their gametogenic cycle. The effect of temperature may be direct by affecting bivalves' metabolic rate, or indirect by affecting the availability of food which increases in summer when temperature is high (Taylor & Venn 1979, Pazos et al. 1997). Both such effects of temperature may be relative to the seasonal cycle of storage and utilization of energy reserves.

Gametogenesis and Biochemical Composition

The gonadal growth in winter to early spring took place at the expense of the stored reserves (mainly glycogen). This was reflected to a negative correlation between the GMI and the glycogen level (Table 1). The gametogenisis in marine bivalves occurs at the expense of the recently ingested food and/or energy stored in various tissues. In the mussel *Mytilus edulis*, glycogen reserves are stored in the mantle (Lubet 1976, Bayne et al. 1982) and are used in the gametogenesis (Gabbott and Bayne 1973). However, in the oyster *Ostrea edulis*, the storage reserves and the gametogenesis take place concurrently (Ruiz et al. 1992b). The relationship between energy storage and gametogenesis within a single species

may depend also upon whether glycogen sufficient to meet the energy requirement for gonadal development, is stored under the feeding condition prior to the gametogenesis. Navarro et al. (1989) reported inter-annual differences in the timing of gametogenesis and the storage cycle of carbohydrate reserves in a population of the cockle *Cerastoderma edule* from Mundaca Estuary (Spain). In fact, gamete proliferation of the cockle population occurred during the expense of glycogen reserves or simultaneously with the accumulation of energy reserves, depending on prior feeding conditions. Such a difference within a species was also observed geographically in the oyster *Crassostrea gigas*. While the glycogen stored is used in the gametogenesis of an oyster population in El Grove (Spain) (Ruiz et al. 1992a), the accumulation of reserve materials and the gametogenesis commenced simultaneously in Korean Waters (Kang et al. 2000). Recently, Luna-González et al. (2000) also found that the scallop *Argopecten ventricosus* uses the available food in the environment more than muscle reserves for the gonadal maturation when the food is abundant, but they use the muscle reserves when the food abundance is poor.

Summer spawning of *S. broughtonii* was followed by a subsequent accumulation period of reserve materials in autumn (from October to December). A great increase in animal tissue weight in autumn was attributed to the rapid accumulation of protein and carbohydrate during that period (Figs. 5 and 6). Glycogen level fell slowly during the course of gonadal development in the winter–spring period. In the present study, the low chlorophyll *a*, food material and food index indicated that both quantity and quality of food were poor during the winter–spring period (from February to May), although a temporary peak in food material was recorded in February (Fig. 3). Therefore, our results indicate clearly that the gametogenesis of *S. broughtonii* in winter–spring depend largely on the glycogen stored during the previous autumn. It is generally accepted that glycogen reserves are the main source of energy in bivalves (Reid 1969, De Zwaan & Zandee 1972) and also may be utilized for the formation of gametes under conditions of nutrient stress (Gabbott and Bayne 1973, Newell and Bayne 1980, Barber and Blake 1981, Beninger and Lucas 1984).

Protein and lipid levels increased steadily during gametogenesis, with maxima prior to spawning. Lipid is converted from glocogen reserves and biosynthesized during the formation of gametes (Gabbott 1975, Lubet 1976). Lipid level may be a good index of gonad maturity (Pazos et al. 1997), because lipid has been considered one of the principal energy sources used during non-feeding embryonic and early larval stages of the bivalves (Holland 1978, Gallager et al. 1986). A positive correlation between the GMI and the lipid level ($\tau = 0.605$, $p < 0.01$) supports these hypotheses. Protein constitutes the major organic component of bivalve oocytes (Holland 1978). Therefore, protein maxima prior to spawning may support this hypothesis. Protein also supports reproduction after carbohydrate and lipid reserves were depleted (Mann & Glomb 1978, Barber & Blake 1981) and constitutes the main reserve during periods of energy imbalance (Gabbott & Bayne 1973, Beninger & Lucas 1984, Navarro et al. 1989). However, the lack of evidence for such roles of protein reserves in the present study may be attributed to the biochemical analyses for pooled tissues. Another possible explanation for the steady increase of protein level in winter–spring is that part of the energy necessary for gametogenesis and maintenance may be supplied by the recently ingested food without intervention of the energy reserves. Analyses for various organs such as striated adductor muscle, digestive gland and gonad will reveal roles of reserve materials in detail, as proposed by Barber and Blake (1981) and Pazos et al. (1997).

In conclusion, *S. broughtonii* from Chinju Bay, a southern coastal bay of Korea, was characterized by a spawning period in summer due to the monocyclic gametogenesis throughout the year. Gametogenesis took place in winter–spring at the expense of reserves accumulated previously in autumn. An inverse relationship between glycogen levels and GMI suggests that carbohydrate played an important role as the gametogenesis fuel. Therefore, this bivalve may be considered a typical conservative species in gametogenic pattern (Bayne 1976).

ACKNOWLEDGMENTS

This work was supported by the Ministry of Maritime Affairs and Fisheries – Special Grants for Fisheries Research and Development Project in Korea. The authors thank anonymous reviewers for helpful comments on an earlier draft of this manuscript. We are also grateful to Ki-Ryung Kim and Mi Kyoung Son for their assistance in biochemical analysis.

ABSTRACT Two species of arkshell ("blood") clams, *Noetia ponderosa* and *Anadara ovalis*, have recently been targeted by watermen on the eastern shore of Virginia for sale to both East and West Coast markets in the United States. Until 1991, fishermen caught both species in the harvest of oysters and hard clams, and discarded them as bycatch with little value. Very little is known about either species of blood clam, and preliminary data from a pilot study in 1993 indicated that they were being over-fished. We conducted a survey in September 1994 in the oceanside lagoon system along the eastern shore of Accomac and Northampton Counties, Virginia, and collected data on density, abundance, habitat preference, age-size and morphometric relationships, and mortality rates for both species of blood clams, as well as some ancillary data on the hard clam, *Mercenaria mercenaria*. The study provides baseline data for establishing management practices and regulations for the blood clam fishery. The total estimated abundance in the study area was about 16 million *N. ponderosa* and 6.4 million *A. ovalis*. Of the clams taken in commercial catches on the oceanside of the eastern shore, *M. mercenaria* constitutes about 84%, *N. ponderosa* 15%, and *A. ovalis* 1%. In our field survey, *M. mercenaria* was the most abundant species (72% of the total catch), followed by *N. ponderosa* (17%) and *A. ovalis* (11%). Densities for blood clams averaged 0.35 clams m^{-2}, or 3,500 clams per hectare, and were highest in shell and shell/mud substrate (1.1 and 1.2 clams m^{-2}, respectively). Growth studies and age-size data show that *A. ovalis* grows about twice as fast as *N. ponderosa* and that market-size *N. ponderosa* (about 56 mm in shell height) may be 8+ years old. We also present information on mortality rates and morphometric relationships for both species of blood clams, and recommendations for maintaining and enhancing the fishery.

KEY WORDS: *Noetia ponderosa, Anadara ovalis*, arkshell, blood clam, growth rate, density, substrate

INTRODUCTION

Since 1991 two species of arkshell or "blood" clams, *Noetia ponderosa* (Say 1822) (ponderous ark) and *Anadara ovalis* (Bruguière 1789) (blood ark), have been harvested by watermen on the eastern shore of Virginia for sale to markets in Washington D.C., New York City, Los Angeles, and Chicago. Long considered a useless incidental catch in the harvest of the hard clam, *Mercenaria mercenaria* (Linnaeus 1758), and the eastern oyster, *Crassostrea virginica* (Gmelin 1791), arkshell clams now constitute a rapidly growing fishery with potential for future development. However, there is very little published information on the life history of either of these species. Chanley (1966) and Chanley and Andrews (1971) described the larval stages of *N. ponderosa* and *Anadara transversa* (Say 1822) in Virginia waters and reported spawning periods of June to December and May through September, respectively. In addition, they stated that *A. transversa* was common in Chesapeake Bay and tributaries with salinities above 15. Loosanoff and Davis (1963) and Loosanoff et al. (1966) also described the larval development of *A. transversa*. McGraw and Castagna (1994) conducted preliminary investigations on growth rates of *A. ovalis* and *N. ponderosa* on the eastern shore of Virginia concurrent with the growth of a blood clam fishery there. Anderson et al. (1985) also reported the potential for a viable blood clam fishery along the South Carolina coast but could not find a market for the clams. Walker (1998) studied the growth and survival of *A. ovalis* in suspended pearl nets in Wassaw Sound, Georgia. The intensive harvesting of blood clams and paucity of data on important factors such as distribution, densities, growth rates, and survival present a problem for management of the fishery in Virginia waters.

Blood clam landings in Virginia (Fig. 1) from 1993 to 1998 (National Oceanic and Atmospheric Administration 2000) show that about 8.9 metric tons of blood clams were harvested in 1993, with a decline to 2.5 metric tons in 1995, and an increase to 10.8 metric tons in 1997. The most logical explanation for the resurgence in tonnage appears to be a change in gear type, from mostly mechanical tongs during the early phase of the fishery to clam dredges after 1996. Landings are reported as wet-meat weights, whereas the clams are usually sold whole, in the shell. Using a conversion factor supplied by the state of Virginia (Iverson pers. comm., Virginia Marine Resources Commission, February, 2000), we estimated that the number of clams range from about 340,000 clams landed in 1995 to 1.5 million clams in 1997.

Most of the blood clams harvested along the eastern shore of Virginia are *N. ponderosa*; however, some *A. ovalis* are included, and buyers make no distinction between the two species. Virginia State fishery regulations concerning the harvest of arkshell clams are currently the same as for hard shell clams, and prohibit dredging from April 1 through December 1. Harvest by mechanical tongs is not regulated by season, and that method is used to continue harvesting during the closed dredging season. Clam fishermen would like to harvest blood clams by dredging year-round to provide consistent supplies to the markets they have developed. They requested a variance from the fisheries regulatory agency, Virginia Marine Resources Commission (VMRC), to permit dredging the arkshell clams during the normally closed season (Terry 1991). However, VMRC denied the request until more information was available on which to base management practices and regulations.

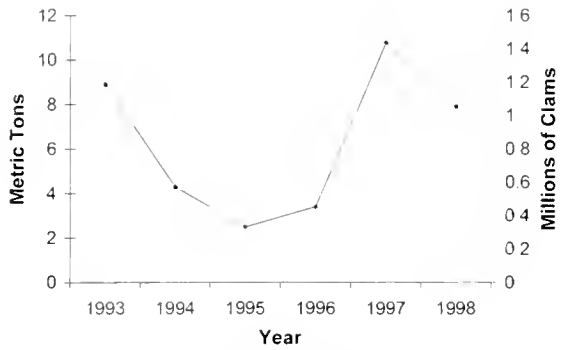

Figure 1. Blood clam landings in Virginia, 1993–1998 (National Oceanic and Atmospheric Administration/National Marine Fisheries Service, http://www.st.nmfs.gov/commercial/index.html).

The number of blood clams sold in retail markets in different regions is difficult to obtain, but two seafood dealers in Washington, D.C. offered some estimates for their stores. One sold 3,000 to 5,000 per week at a price of $2.50 to $3.00 (U.S.) per dozen (Pruitt pers. comm., Washington, D.C., 1993). Another company sold about 2,000 blood clams per week from about November through March for about $3.00 to $4.00 per dozen (Martin pers. comm.,Washington, D.C., 1993). Prices usually range from $0.11 to $0.18 per clam (Bishop pers. comm., Oak Hall, VA, 1996); however, watermen reported receiving from $0.07 to $0.25 per whole clam, depending on the size and demand. One reportedly received $0.50 per clam by selling the clams directly from his boat (Annis pers. comm., Willis Wharf, VA, 1993).

Blood clams from Virginia are sold primarily in ethnic markets in the U.S. and are eaten raw and cooked. Both species have a somewhat bitter taste and contain the blood pigment hemoglobin, which gives the flesh a blood-red color (Abbott 1968, Yonge and Thompson 1976). These attributes may explain why they are not usually eaten in the U.S.; however, various ark species (also called blood cockles in some countries) constitute significant fisheries in many other parts of the world, including China, West Africa, Japan, Mexico, Tanzania, India, Thailand, Malasia, and Taiwan (Bae 1986, Baqueiro 1980, Broom 1983, Broom 1985, Guo et al. 1999, Ismail 1986, Kayombo 1993, Narasimham 1969, Narasimham 1988, Nie 1990, Sahavacharin et al. 1988, Ting 1984, Wong and Lim 1985). Prior to 1950 there were also substantial harvests of *Arca noae* (up to 685 tons per year) from the Adriatic Sea (Hrs-Brenko 1980).

The ponderous ark (*N. ponderosa*) has a heavy, thick shell, is ubiquitous along the oceanside of the eastern shore of Virginia, and aggregates in shell debris or "shell hash" where juveniles attach by a prominent byssus to whole shells and pieces of shell (McGraw and Castagna 1994, McGraw et al. 1996). This species ranges from Virginia to the Florida Keys and in the Gulf of Mexico from Key West to Texas. Virginia is thought to be the northernmost extension of the range, and shells found north of Virginia are probably fossils (Abbott 1954). Because they have no siphons, as some other clams do, ponderous arks are usually found at the substrate surface, making them very accessible to dredges and tongs. Market sized *N. ponderosa* may include animals over ten years old (McGraw et al. 1996).

The blood ark (*Anadara ovalis*) is found from Cape Cod to the Gulf of Mexico, the Caribbean, and West Indies (Abbott 1954, Gosner 1978) and occurs subtidally from shallow water to 45 m both in shell and muddy substrates. It has a much thinner shell than the ponderous ark. In salinity tolerance studies, Castagna and Chanley (1973) found that *A. ovalis* and *N. ponderosa* generally functioned better in salinities exceeding 20.

The primary purpose of our study was to gather data on the growth rate, size-frequencies, ages, densities, abundance, and survival of blood clams on the eastern shore, and to make these data available to fisheries management agencies for consideration in overseeing the fishery. Unlimited harvesting, coupled with the slow growth rate of *N. ponderosa* and insufficient recruitment, could eventually lead to depletion of blood clam populations if present harvest practices persist.

METHODOLOGY

The study consisted of four main parts: (1) conducting a field survey to obtain data on density, substrate preference, distribution, abundance, and mortality rates for the two species of blood clams in the tidal lagoons of the eastern shore of Virginia; (2) determining growth rates from age-size relationships using the acetate peel technique; (3) collecting fisheries catch data from local watermen; and (4) following the growth rates of cohorts of *A. ovalis* and *N. ponderosa* over a 2-y period. Although the primary emphasis of the study was on blood clams, we collected some data for the hard clam (*Mercenaria mercenaria*), and some of that information is also included for comparison, since it is the primary species harvested.

Field Survey

We conducted a field survey aboard a commercial fishing vessel rigged with mechanical tongs during September 1994. The main sampling area (Fig. 2) was the oceanside of the eastern shore of Virginia from the Great Machipongo Inlet to Wachapreague Inlet, or the general area between longitudes 75°42′–50′W and latitudes 37°20′–38′N. We employed both random and systematic sampling techniques, depending on the area being sampled. In Hog Island Bay, depth of water permitted more random sampling, both in channels and over mud flats, whereas the more northern part of the study area was better suited to systematic sampling in channels.

We determined random sampling sites by setting up a grid overlay (800 m × 800 m blocks) of the Hog Island Bay area (NOAA chart #1221) and used random number tables to determine which blocks we would sample. We took three samples within each chosen block, and the sampling locations within the block

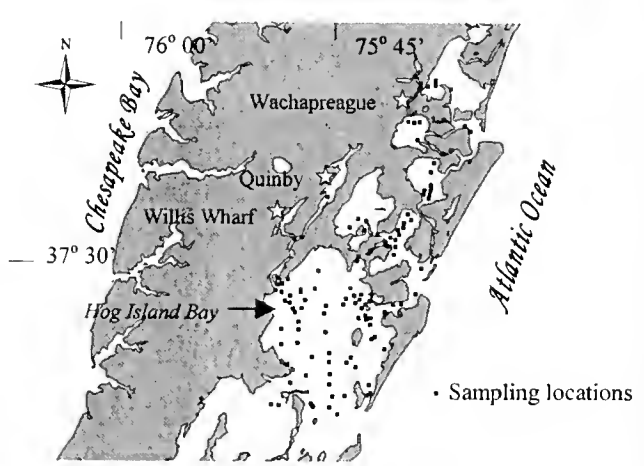

Figure 2. Map of study area.

constituted one station. If water depth in a block was too shallow, we eliminated the sampling site and selected additional random numbers until another suitable block was chosen.

In addition to the blocks chosen by random numbers, we included portions of some of the following tidal creeks and channels in a systematic sampling plan: Swash Creek, Sandy Creek, Sloop Channel, Parting Creek, Machipongo River, Great Machipongo Channel, Quinby Inlet, Sand Island Channel, Millstone Creek, and Wachapreague Inlet. In tidal creeks and channels we took three samples approximately every 0.5 miles or 900 m, usually in the immediate vicinity of channel markers to more precisely locate positions on navigation charts. Channel samples usually spanned the channel or creek along transects, with one sample from the middle and one from each side. We sampled a total of 119 stations.

We used mechanical tongs for sampling gear instead of a dredge because tongs cover a discrete area, 1.12 m^2, penetrate into the substrate about 15 cm, and retain more substrate when retrieved from the bottom. Retention of substrate and small clams was assured by lining the tongs with 1 cm^2 plastic mesh. Area is a more pertinent measurement than volume for assessing densities of blood clams because the clams inhabit the upper 6–8 cm of substrate and are easily caught with tongs. We placed samples in plastic bags or buckets and sorted them on shore.

We processed samples on shore by washing them through 1 cm^2 mesh screens (corresponding to the mesh size lining the tongs) and counted and measured all clams (height, length, and depth) to the nearest mm with vernier calipers. Height is defined as the distance between the dorsal hinge (umbo) and the ventral lip of the clam (Fig. 3), and length is the distance from the anterior end to the posterior end. Depth or thickness is the greatest distance between the right and left valves. We used morphometric data to construct size-frequency distributions for both species of blood clams as well as to determine relationships between height, length, and depth for *N. ponderosa* and *A. ovalis*. We also weighed some clams to determine the correlation between height, whole weight, and wet meat weight.

Our preliminary observations (McGraw and Castagna 1994) indicated that *N. ponderosa* is found almost exclusively in areas with shell and shell debris. Because random survey samples contained varying substrates, we could evaluate habitat preferences for *N. ponderosa* and *A. ovalis*. We qualitatively placed substrate material in each sample into the categories used by Haven et al. (1981) (i.e., mud, sand, shell, shell/mud, shell/sand, and sand/mud) and provided areal estimates of each. Space limitations of the vessel and the volume of substrate in some samples dictated that only portions of samples (i.e., sub-samples) be retained for sorting. In those instances, we noted sub-sample proportions, along with other data, and factored those into the density calculations during data analyses to obtain adjusted densities. We estimated densities for each species at each station based on the number of clams obtained per sample and surface area covered by the tongs (i.e., approximately 1.12 m^2).

Analysis of field data showed that the general distribution of clams was clustered or aggregated (i.e., non-normally distributed), as evidenced by coefficients of dispersion > 1 (Sokal and Rohlf, 1969). Therefore, we transformed density data using log (X + 1) transformation according to the method discussed in Zar (1974) and Sokal and Rohlf (1969) before we applied analysis of variance (ANOVA) or other statistical tests (e.g., to test for differences between mean densities among substrate types). After transformation, we calculated clam densities by dividing the number of clams caught in each sample by the area covered by the mechanical tongs (i.e., 1.12 m^2). Then we tested mean densities of clams (both species combined) found in the various substrates using ANOVA (Sokal and Rohlf 1969) and the Student-Newman-Keuls (SNK) test (Zar 1974) to determine which means, if any, were significantly different ($\alpha = 0.05$). We analyzed data further according to substrate type and water depth (i.e., deep water/channels or mud flats/shallow areas).

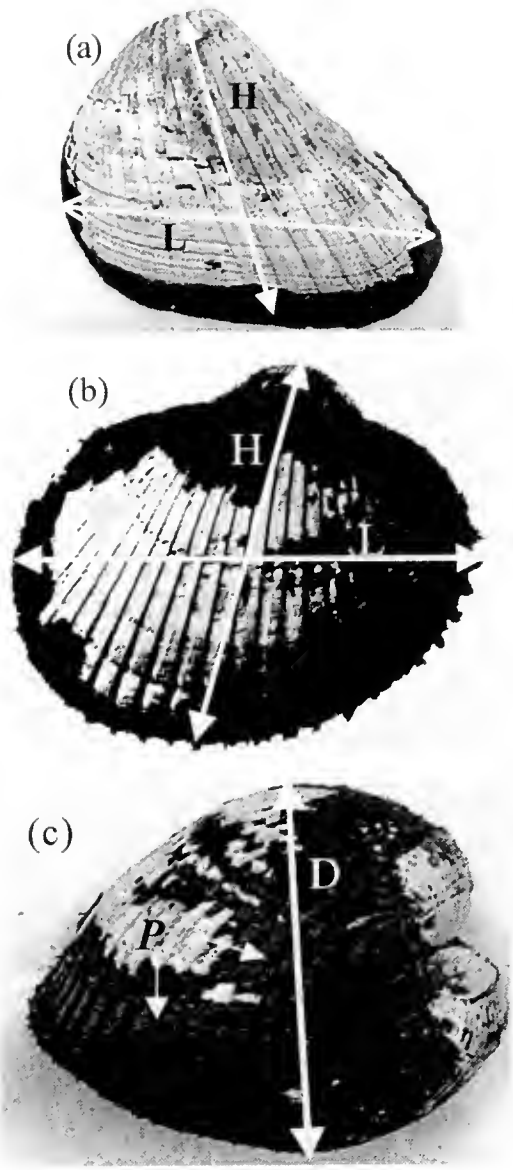

Figure 3. ***Noetia ponderosa*** **(a) and** ***Anadara ovalis*** **(b) showing length (L) and height (H) dimensions; (c)** ***Anadara ovalis*** **showing depth (D) dimension and periostracum layer (*P*).**

Where substrate type was the same for two or three samples from a station, we averaged those for each station; if substrate types differed, we treated them as separate samples. Therefore the number of samples for comparing species by substrate types was 169 instead of 119.

Shell Aging

We used acetate peels on different sizes of blood clams to determine age more precisely and to estimate the maximum lon-

gevity of the clams. The technique has long been used by paleontologists (Rigby and Clark 1965), but has proven effective in age determination for several species of bivalves (Ropes and O'Brien 1979, Ropes 1984, Ropes 1987, Kennish 1980). We specifically employed Farrow's (1971) method, which eliminates the step of embedding shells in epoxy resin. In addition, we modified Farrow's (1971) method by using thick (1.56 mm) acetate and cutting it into 7.6 cm × 2.54 cm pieces (i.e., the size of microscope slides) that could fit easily onto the mechanical stage of a compound microscope.

Several authors have discussed shell microgrowth patterns in detail, including Pannella and MacClintock (1968), Rhoads and Pannella (1970), and Lutz and Rhoads (1980). Age and size data can be applied to size distribution data through back-calculation procedures to create age frequency distributions, thus providing a better understanding of the population structure (Robson and Chapman 1961, Gulland 1966, Ricker 1975). We determined ages for all blood clams from the field survey and increased sample size and accuracy by supplementing these with data from previous studies and additional clams purchased from local watermen. Then we constructed Von Bertalanffy growth curves (Ricker 1975) for both species of blood clams.

Mortality Rates

We used articulated clam shells from survey samples to estimate annual age-specific and instantaneous mortality rates for both species. Some bivalves remain articulated for a time after death before the hinge ligament deteriorates and the valves separate. These can be used to help estimate natural mortality (Dickie 1955, Buckner 1984) by dividing the number of articulated shells by the sum of live clams plus articulated clams for different size/age groups. There are no data documenting the length of time for deterioration of the hinge ligament for either *N. ponderosa* or *A. ovalis* in Virginia waters, and all mortality rate calculations are based on an assumed time period of one year for disarticulation. We computed instantaneous mortality rates using the equation $(Z) = -\log E (1 - A)$, where A = the number of living clams in an age group and E = 2.718, the base of natural logarithms (Ricker 1975). First, we applied age-length data from acetate peels to the size distribution of living and articulated clams from the survey and determined the number of clams in each age-size class. Then we divided the number of articulated shells in a given age-size category by the number of live clams to arrive at an age specific or annual mortality rate expressed as a percentage.

Commercial Catch Data

Mr. David Bishop (Oakhall, VA, Accomac County) collected and recorded data on the proportion of blood clams versus hard clams from many of his tong catches over a three-month period, from September through November, 1994. We used height-frequency data from his catches for comparison with data from 1993 fisheries samples to help determine if average clam size in commercial catches was decreasing and also to more accurately assess the percentage of blood clams in clam harvests.

RESULTS AND DISCUSSION

Field Survey Results

Clam Density and Abundance

We took a total of 355 individual samples at 119 stations, which yielded adjusted totals of 86 *N. ponderosa*, and 55 *A. ovalis*. The 119 stations included random stations, mostly in Hog Island Bay, as well as non-random, or systematic stations, in the northern part of the study area, taken mostly in channels or creeks. Before combining data from all stations, we first ascertained (using transformed data and ANOVA) that there was no significant difference ($\alpha = 0.05$) in mean clam densities (total densities or by species) between random and non-random stations.

For the non-random (mostly channel) stations, we also tested to see if there was any correlation between clam densities and station location within particular waterways, as defined by distance (nautical miles) from the entrance of a channel (Scheaffer et al. 1996). We found no correlation or trends (maximum $r^2 = 0.06$ in the Great Machipongo Channel) and combined all non-random channel stations for further analyses.

Average density (mean ± standard error = $\bar{X}$ ± S.E.) at all stations ($n = 119$) was 0.21 ± 0.06 clams m^{-2} for *N. ponderosa* and 0.14 ± 0.07 clams m^{-2} for *A. ovalis*. Total average blood clam density was 0.35 ± 0.10 clams m^{-2}. Compared to hard clams, 17% of the total catch was *N. ponderosa* and 11% was *A. ovalis*.

To compare densities by substrate, we averaged densities for each substrate at each station; if station samples contained two or more different substrates, those were considered separate samples. We did this to minimize any pseudoreplication (Hurlbert 1984) and to avoid combining samples across substrates. Therefore, sample size for comparing substrates was 169 (i.e., at some stations not all samples were of the same substrate). In addition, because the mean densities are weighted differently when categorized by substrate type, they are slightly different from those calculated for stations, where the sample size was 119. The proportion of different substrate types among stations was as follows: mud = 35%, $n = 59$; sand = 11%, $n = 18$; sand/mud = 21%, $n = 36$; shell/mud = 17%, $n = 29$; shell/sand = 6%, $n = 11$; and shell = 10%, $n = 16$.

Mean clam densities varied among substrate types (Fig. 4) and were highest in shell (1.24 ± 0.4 clams m^{-2}) and shell/mud substrates (1.12 ± 0.49 clams m^{-2}). *Noetia ponderosa* accounted for most or all clam densities in those two substrates. For example, mean density of *N. ponderosa* was highest in shell/mud substrate (1.12 clams m^{-2} ± 0.49) and shell (0.79 ± 0.36), whereas *A. ovalis* densities were highest in shell substrate (0.45 ± 0.24 clams m^{-2}) and mud substrate (0.19 ± 0.15). The highest density of *N. ponderosa* we observed in a single sample was 13.4 clams m^{-2} at a station in the Great Machipongo Channel (intracoastal waterway); the mean density at that station was 4.46 clams m^{-2}. The highest

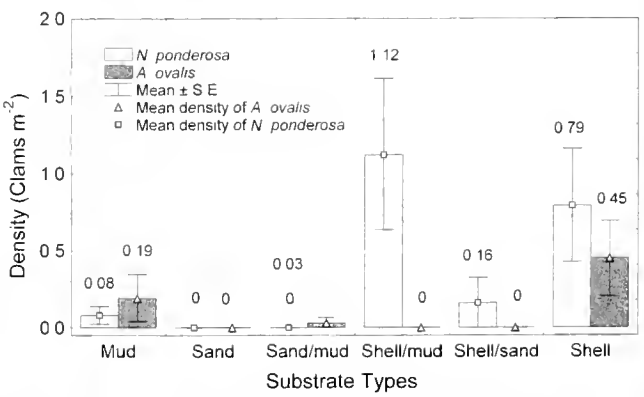

Figure 4. Comparison of *A. ovalis* and *N. ponderosa* densities (clams m^{-2}) in various substrates from the eastern shore of Virginia.

density of *A. ovalis* was 15.0 clams m^{-2} from a sample in The Deeps Channel, a branch of the Great Machipongo Channel.

After transforming density (i.e., log [X + 1]), we compared mean blood clam densities for the six substrate types using ANOVA ($\alpha = 0.05$) and the Student-Newman-Keuls test (Zar 1974) to determine which, if any, means were different. There was a significant difference in mean total blood clam densities among substrates ($P < 0.001$). There were no significant differences in mean total blood clam densities between shell and shell/mud substrates, or between mud substrate and shell/sand, sand/mud, or sand (Table 1 and Fig. 4). However, there were significant differences in mean densities between both shell or shell/mud substrates and all other substrate types ($P < 0.001$). Results are summarized as follows: (shell = shell/mud) ≠ (mud = shell/sand = sand/mud = sand).

Next, we compared densities for both species by substrate type. Results were the same for analyses of *N. ponderosa* densities by substrate types as for both species combined. However, density of *A. ovalis* in shell substrate was significantly different from those in all other substrates, i.e., shell ≠ (shell/mud = mud = shell/sand = sand/mud = sand). The higher densities of clams in shell and shell/mud substrates suggests that shell is important either for attachment, protection from predation, or both.

We estimated the abundance of clams (Table 1) by using substrate data from Haven et al. (1981) and multiplying the density of clams found in various substrates by the number of hectares of that substrate for the study area. That is, $A_t = \Sigma$ (Ds × ha), where A_t = the total abundance of clams in the study area; Ds = the total mean density of clams in a given type of substrate; and ha = number of hectares of a given substrate in the study area. Haven et al. (1981) estimated the following amounts (converted to hectares here): shell = 116 ha; shell/sand = 838 ha; shell/mud = 1,002 ha; sand = 1,523 ha; mud = 2,933 ha; sand/mud = 1,057 ha. The combined areal totals from Haven et al. (1981) are for Burton's Bay, Bradford Bay, Swash Bay, Upshur Bay, Major Hole Bay, Revel Island Bay, Hog Island Bay (above and below North Channel), Ramshorn Bay, and Sand Shoal Channel. Total estimated blood clam abundance in the study area (Hog Island Bay, Burton's Bay, and Bradford Bay and contiguous waterways) was 22 million blood clams. Total estimated abundance by species is as follows: *N. ponderosa*, about 16 million; *A. ovalis*, about 6 million. The proportions are based on those from the field survey (Table 1) in which *N. ponderosa* had an average density of 0.31 clams m^{-2} ± 0.09 ($n = 169$), and *A. ovalis* of 0.12 clams m^{-2} ± 0.06 ($n = 169$) over all substrates.

We examined clam densities in relation to water depth (i.e., channels or mudflats). Of the 119 stations sampled, 67 were in channels or locations with a water depth >2 meters, and 52 were over mudflats, or in shallower water. Using log transformation and Student's *t*-test (Zar 1974), we determined that there was no significant difference ($\alpha = 0.05$) in mean total blood clam densities (Fig. 5) between channel/deep water stations (0.48 ± 1.3) and mud flat stations (0.19 ± 0.10), even though channel stations had twice the density of shallower ones. The relatively high variances for both means affected results and $P = 0.052$, just slightly more than the stated level of significance.

Although mean clam densities were higher at channel/deep water stations, there were no significant differences ($P > 0.10$) between mean densities in channel and mud flat stations for either species (Fig. 5). One explanation for the higher density of clams in the channels/deep water stations might be that clams are sloughed off or eroded from the sides of the channels, along with substrate, and aggregate in the bottom of the channel. In some of the tidal creeks currents may expose areas of shells, providing more attachment sites for blood clams, particularly *N. ponderosa*.

Size-Frequency

Average shell height for blood clam species (Fig. 6) were: *N. ponderosa*, 42.6 mm (± 2.2, $n = 43$) and *A. ovalis*, 25.1 mm (± 0.2, $n = 29$). There were relatively few small *N. ponderosa* (i.e., <25 mm, or about 2 years old) taken in survey samples. This could simply be the result of sampling variability, but could also indicate that recruitment may be low or that mortality rates may be high during the first year after settlement. Most of the hard clams (*M. mercenaria*) in samples were also larger, 60 to 100 mm in height (75.3 ± 1.2, $n = 146$), and sizes were more normally distributed (Fig. 6c). In contrast, most of the *A. ovalis* (Fig. 6a) were 0+ to 2 years old, with very few older, larger clams in samples.

Articulated Shells and Mortality

After calculating Von Bertalanffy growth curves for both species of blood clams, we applied age-length data to articulated shells, put them into age categories, and estimated annual and instantaneous mortality rates (Table 2) as previously described. In the absence of published or other data on the length of time for

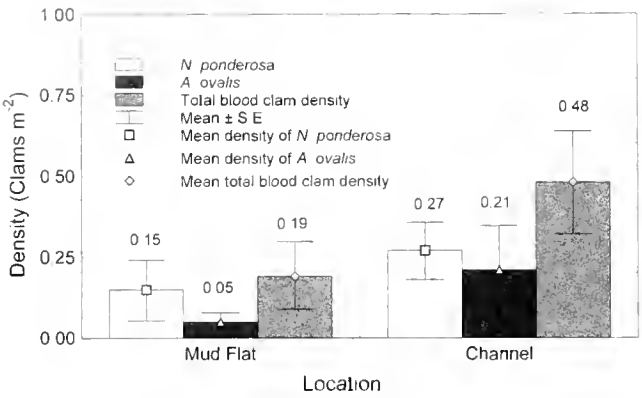

Figure 5. Comparison of blood clam densities (clams m^{-2}) on mudflats and in channels from the eastern shore of Virginia.

disarticulation of shells for either species of blood clam, we assumed a period of one year. Because blood clam density in the study area was relatively low, there were some age groups for which no articulated clams appeared in samples and thus mortality rates were zero. Despite the gaps in data, we think that the mortality estimates provide some insight into basic mortality trends for *N. ponderosa* and *A. ovalis*.

The annual mortality rate (Fig. 7) for 0+ to 1 year *A. ovalis*, calculated using articulated shells in samples, is 86%, then decreases to 30% for the 1+ to 2 year class. Because there were only four articulated clams in the age 3+ category, all less than 48 mm, we pooled the data for a better estimate of mortality rates. The average was 80% for age 3+ clams. Distributed over the estimated maximum life span of six years for *A. ovalis*, the annual mortality rate would be about 27% per year for clams over age 3+. There were no articulated shells in the 2+ to 3 year size range in our samples, so the annual mortality rate for that year class of *A. ovalis* was zero. The increase in mortality rates for older (>3+) clams may be due to senescence or other factors such as disease, or synergistic effects involving spawning and higher water temperatures in the summer. Toyo et al. (1978) (as cited by Broom 1985) reported a sudden mass mortality of a species of *Anadara* (probably *A. broughtoni*) in Japan due to a rapid rise in water temperature above 25°C.

TABLE 2.

Mortality rates (%) and instantaneous mortality rates (Ẑ) for *A. ovalis* and *N. ponderosa*, based on articulated clam shells.

Year class	No. articulated shells	No. live	Total	Mortality (%)	(Ẑ)
A. ovalis					
0–1	70	11	81	86.4	2.0
1+–2	7	16	23	30.4	0.4
2+–3	0	1	1	0.0	0.0
>3+[a]	4	1	5	80.0	1.6
N. ponderosa					
0–1	8	1	9	88.9	2.2
1+–2	3	2	5	60.0	0.9
2+–3	0	9	9	0.0	0
3+–4	0	3	3	0.0	0
4+–5	0	3	3	0.0	0
5+–10[b]	6	11	17	35.3	0.1
10+–15[c]	5	14	19	26.3	0.1

[a] Pooled because of low number of clams in age category. Mortality is estimated to be about 27% per year and (Ẑ) is estimated to be about 0.54 per year for age 3 +– 6 clams.

[b] Mortality is estimated to be about 7% per year and (Ẑ) is estimated to be about 0.1 per year for age 5 +– 10 clams.

[c] Mortality is estimated to be about 5.3% per year and (Ẑ) is estimated to be about 0.1 per year for age 10 +– 15 clams.

Although our estimates are based on relatively few articulated clams, we feel that the data reflect the actual situation, because very few large *A. ovalis* (>50 mm in height) are taken in commercial clam catches and most seem to die before reaching six years of age. A similar phenomenon has been observed for the bay scallop, *Argopecten irradians*, in which about 80% die between months 13–16 (Castagna 1975, Castagna and Duggan 1971). Observations of large *A. ovalis* (i.e., ~53 mm in height) held in flowing water tables indicate that they are sensitive to water temperatures and begin to die above about 27°C, whereas large *N. ponderosa* in the same water tables are not affected. Some watermen have told us that some *A. ovalis* in their catches seem to gape much more readily than *N. ponderosa* during warm weather. It appears that few *A. ovalis* live longer than six years in the Virginia lagoon system, and that mortalities of older clams are exacerbated by high water temperatures.

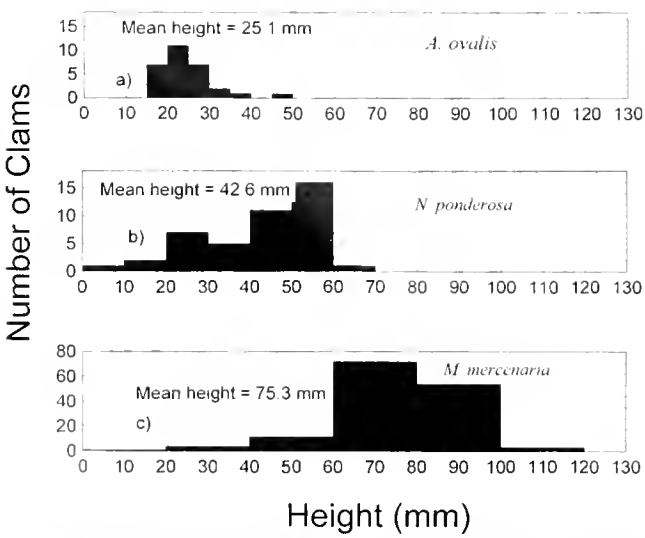

Figure 6. Height frequency distribution for *A. ovalis*, *N. ponderosa*, and *M. mercenaria*.

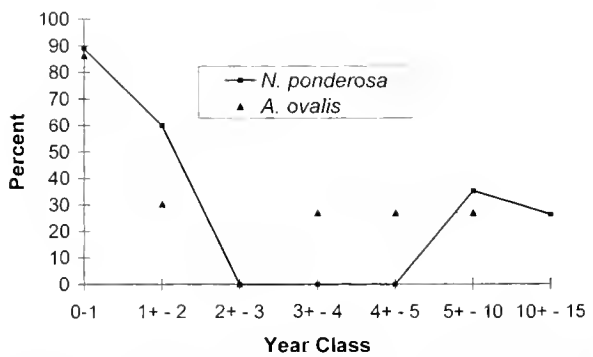

Figure 7. Comparison of mortality rates for *N. ponderosa* and *A. ovalis*.

Walker (1998) reported mortality rates of about 55% for small and medium (<20 mm in length) *A. ovalis* held in pearl nets in Georgia (i.e., from an initial group of 78 clams down to 35) during the first year; average mortality rate for the same groups was about the same during the second year of growth (i.e., 16 out of 35 clams survived). Presumably the pearl nets decreased mortality rates from siltation and predation, and therefore rates were lower than those calculated in our field study. Walker (1998) also stated that the life span for *A. ovalis* in Georgia waters is about three years, whereas we estimated that the life span is six years in Virginia.

Annual mortality rates for *N. ponderosa* (Table 2 and Fig. 7) were highest for the 0+ to 2-year-old groups (89% and 60%, respectively). For convenience sake, and because of small sample sizes, we grouped the 5+ to 10-year-classes and 10+ to 15-year-old clams to determine mortality rates. The cumulative annual mortality rate for the 5+ to 10-year-old group was 35% over the five year period, or about 7% per year; for the 10+ to 15-year-old clams, it was 26%, or about 5% per year.

There were no articulated *N. ponderosa* for the 2+ to 5-y age classes in samples, suggesting a decreasing mortality rate for those age classes. This trend could be a result of increasing size and lower densities during the first two years, as a function of competition for food and space.

Morphometrics

The data used for morphometric relationships are from several sources, including growth studies, fisheries samples, survey samples, and extra clams purchased for shell aging studies. We examined the relationships of several variables: shell height, length, depth, whole weight, and wet weight.

The relationship between valve height and length for *N. ponderosa* (Fig. 8a) is described by the regression equation: $L = 1.22H + 1.73$ ($r^2 = 0.99$) where L = length in mm, H = height in mm, and r^2 = coefficient of determination. Height and shell depth were also linearly related (Fig. 8b) as described by the regression equation $D = 0.98H - 2.57$ ($r^2 = 0.99$), where D = depth of the clam in mm.

Relationships between height and whole (i.e., shell + meat) or wet meat weights were nonlinear (Figs. 8c and 8d). For example, the relationship of height and whole weight is described by the allometric equation of the form $W = aH^b$ (Fig. 8c) where W = whole weight of the clam in grams, H = height in mm, and a and b are allometric coefficients (a = 0.0006 and b = 3.06). Transformed to the linear form, this equation is: $\log W = b\log H + \log a$. Wet meat weight and height were likewise nonlinearly related by the equation $M = aH^b$, where M = meat weight, $a = 0.001$, and $b = 2.52$ (Fig. 8d). The coefficient of determination, $r^2 = 0.88$, is slightly lower than that for height and whole weight, since meat weight determinations are subject to more sampling error, mostly because of varying amounts of water loss. Mean shell weight was 46.8 g (± 36.3, $n = 132$), and mean whole wet weight of *N. ponderosa* was 60.5 g (± 44.06, $n = 132$), or about 77% of the total weight. Mean meat weight (13.6 g) was about 23% of the total weight of the clams sampled.

Relationships of shell height to length or depth for *A. ovalis* were linear (Figs. 9a and 9b). Unlike *N. ponderosa*, shell length in *A. ovalis* changes little in relationship to the height, and most clams are, as the name ("*ovalis*") implies, oval or nearly round. By comparison, increase in shell depth in *A. ovalis* per increase in shell height is proportionately smaller than that in *N. ponderosa*, in which shell depth is almost equal that of height. For *A. ovalis*, shell depth is about 70% of shell height.

The relationship of whole weight and height in *A. ovalis* (Fig. 9c) is best described by the curvilinear equation: $W = aH^b$, where W = whole weight in grams, $a = 0.0003$, and $b = 3.14$ ($r^2 = 0.97$). As with *N. ponderosa*, the correlation ($M = 4E^{-05}\ H^{3.33}$) between height and wet meat weight (Fig. 9d) was more variable than with whole weight, and the coefficient of determination was slightly lower ($r^2 = 0.89$) than for the regression of height and whole weight. Mean whole weight for the *A. ovalis* sample was 34.2 g (± 21.2, $n = 139$), mean shell weight was 22.7 g (± 14.2,

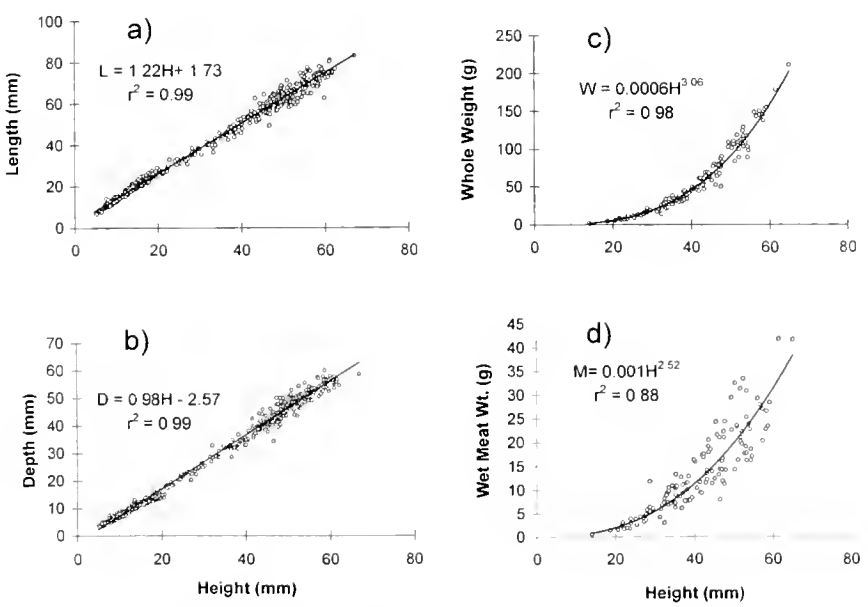

Figure 8. Regression of height versus length (a), depth (b), whole weight (c), and wet meat weight (d) for *N. ponderosa*. Data are from field surveys, commercial fisheries samples, and growth studies ($n = 540$ for a and b; $n = 132$ for c and d).

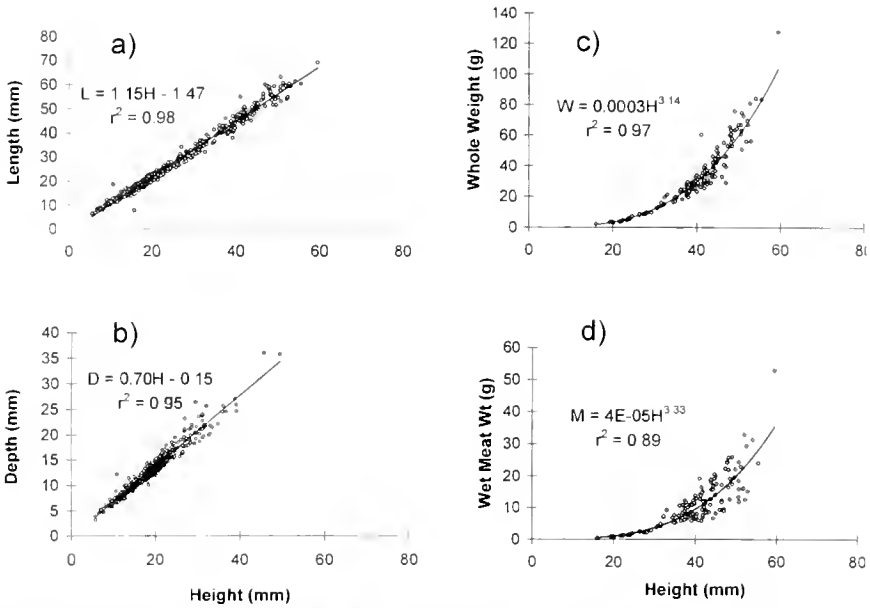

Figure 9. Regression of height versus length (a), depth (b), whole weight (c) and wet meat weight (d) for *A. ovalis*. Data are from field surveys, commercial fisheries samples, and growth studies (n = 778 for a; n = 641 for b; n = 139 for c and d).

n = 139), and mean wet meat weight was 11.5 g (± 8.2, n = 139). Therefore, shell weight in *A. ovalis* constituted about 66% of total weight, and meat weight 34%, or an average of about 10% more meat weight for a given size than in *N. ponderosa*.

Age-size Relationships

We prepared acetate peels from clams taken in the field survey, augmented with clams purchased from fishermen. Some data from growth studies (1992 to 1994) were incorporated as baseline data points for 1- and 2-y-old *A. ovalis* and *N. ponderosa*. We fit age-length data to the Von Bertalanffy growth equation:

$$L_{(t)} = L_{\infty} (1 - e^{-kt})$$

where $L_{(t)}$ is length at time t; L_{∞} is the asymptotic, or maximum theoretical length; and K is a growth constant indicating the rate at which L_{∞} is approached. The L_{∞} and K estimates for *N. ponderosa* (Fig. 10a) are: L_{∞} = 71.5 mm and K = 0.24 (r^2 = 0.94). Both of these parameters are very similar to those given by Cahn (1951) for *A. granosa bisenensis* in Japan.

Mean length of *N. ponderosa* from a commercial fishery sample in 1992 was about 70 mm. Our data indicate that clams >70 mm in length would be 10+ years old. Samples of commercial catches (taken in 1994) from the same vicinity (Parting Creek) showed that the average length of *N. ponderosa* was about 56 mm, a decrease of about 14 mm, or the size of clams of about age 5+. In addition, mean length for *N. ponderosa* in field survey samples was about 54 mm, which also indicates that the older clams are being depleted, and smaller, younger clams are now being harvested. It is possible that some of the clams harvested are older, stunted clams; however, the size ranges for different age groups in the growth model suggest that this is not the case.

The Von Bertalanffy model also provides a good fit for age and size data for *A. ovalis* (Fig. 10b). Values for L_{∞} and K are 57.5 and 0.45, respectively (r^2 = 0.83). Mean length for *A. ovalis* taken in the field survey was 27 mm, or about 1+ year-class clams, while mean length for *A. ovalis* in 1994 commercial fisheries samples was 56.5 mm, or 5+ years old. We obtained only five *A. ovalis* over five years in age in survey samples, which suggests that this species does not live very long in this geographic area. This is also corroborated by the mortality data from articulated *A. ovalis* shells, and from laboratory observations where large *A. ovalis* held in water tables died as ambient water temperatures approached 27°C.

Commercial Fisheries Catch Data

Catch data from a commercial fisherman on the eastern shore (D. Bishop, unpubl.) showed that *M. mercenaria* constituted an

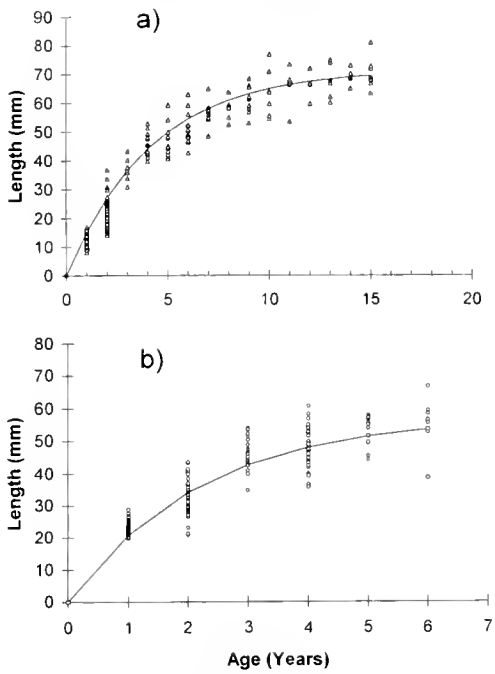

Figure 10. Von Bertalanffy growth curve for *N. ponderosa* (a), n = 379, and *A. ovalis* (b), n = 211, from the eastern shore of Virginia. See text for equations.

average of about 78% of his catch with mechanical tongs, and blood clams (*N. ponderosa* and *A. ovalis* combined) 22% for the period of September to November 1994. The percentages of blood clams in catches for those three months were about 18% for September, 21% for October, and 26% for November. The species distribution was similar to that from the field survey samples (i.e., about 72% *Mercenaria* and 28% blood clams). Average daily catches (Fig. 11) for September, October, and November, 1994 were: 4,373, 3,873, and 3,642 clams per day, respectively.

The estimated average catch per unit effort (i.e., clams in one tonging effort, covering 1.12 m^2) during two days of fishing was 9.72 (n = 540) and 3.6 clams (n = 720), respectively, for an overall mean of about 6 clams per tonging effort (n = 1,260). This equates to an average density of 5.4 clams m^{-2} in the harvest area. The average heights of *A. ovalis* and *N. ponderosa* from subsamples of September to November catches were 34.0 mm and 44.7 mm, respectively (Figs. 12a and 12b). The mean height for *N. ponderosa* was less than that for the commercial fishery sample taken in 1992 (70 mm) and the Parting Creek sample (56.0 mm) taken in 1993. The decrease in average size may indicate that overfishing is occurring.

During December 1994 and January 1995, Mr. Bishop worked in an area just north of Wachapreague, VA (Gargatha Creek) and reported catching almost all *A. ovalis*, the highest percentage catch of that species of which we are aware. His observation is noteworthy because of the normally small percentage of *A. ovalis* in catches, and indicates that small, dense beds of *A. ovalis* exist in some isolated locations. The average height for *A. ovalis* from the January sample in Gargatha Creek was 40.2 mm (Fig. 12c). Most of the clams were in the 30–40 mm size range (= 33 to 44 mm in length), or >3+ years old. The absence of 0+ year-class *A. ovalis* in commercial fisheries samples may simply reflect the difficulty in seeing and collecting very small clams in the mud and debris which accompany catches, or it may also indicate low recruitment and/or high mortality rates. Another, more probable explanation is the fact that small *A. ovalis* are epiphytic. During our study, the easiest place to find 0+ year-class *A. ovalis* was enmeshed in bryozoan and hydrozoan colonies attached to commercial mollusc floats near Quinby or Wachapreague Inlets.

CONCLUSIONS

Survey data provide information about the species composition of the blood clam fishery on the Eastern Shore of Virginia. The hard clam, *M. mercenaria*, constitutes the majority of the catch (72%), with *N. ponderosa* accounting for about 17%, and *A. ovalis*

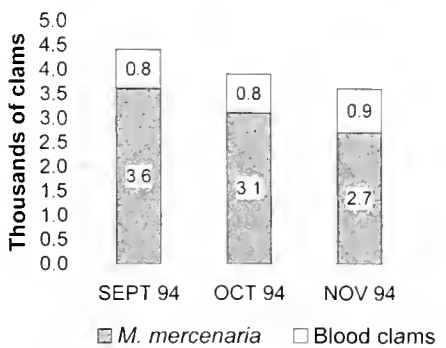

Figure 11. Average daily catch of blood and hard clams (*M. mercenaria*) by a fisherman on the eastern shore of Virginia (Sept.–Nov. 1994).

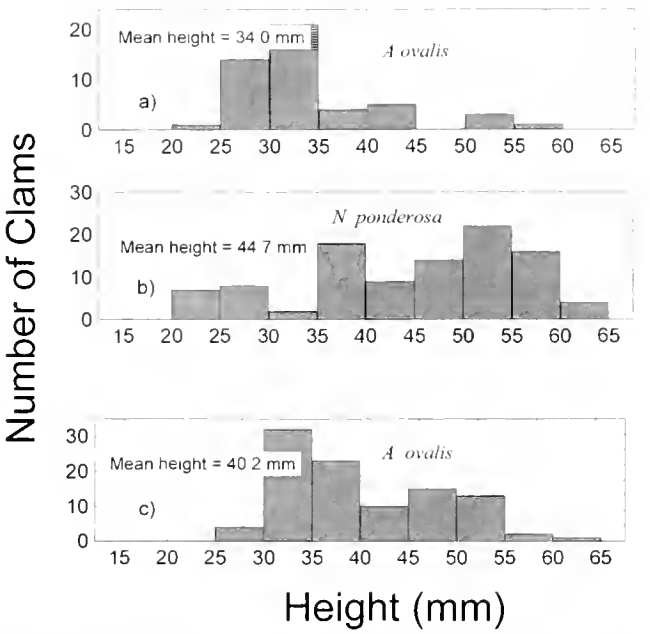

Figure 12. Height frequency distributions for *A. ovalis* (a) and (c) and *N. ponderosa* (b) from Quinby and Wachapreague, Virginia.

11%. However, age-length relationships clearly show that *N. ponderosa*, even though it is more abundant than *A. ovalis*, is a relatively slow-growing species, and may not be suitable for a commercial fishery with high exploitation rates. *Anadara ovalis* grows faster but appears to have a high mortality rate in most areas, as indicated by the relatively few, small ones that were taken in survey samples, the low percentage taken in commercial catches, and field experiments (McGraw et al. 1998).

We estimated abundance for *N. ponderosa* and *A. ovalis* to be about 16 million and 6.4 million clams, respectively, in the general area surveyed. Catch estimates range up to 1.5 million blood clams harvested annually in the survey area. Although this is about 15% of the estimated abundance, we are concerned that if fishing continues unabated, blood clam populations could be decimated within a few years, particularly in light of data showing that *N. ponderosa* grows so slowly and observations that settlement is very sporadic. Survey data as well as samples of commercial landings from the Great Machipongo River and other areas show a decrease in average size of *N. ponderosa*, indicating that *N. ponderosa* is currently being overfished and that there is a need to re-evaluate current policies governing the blood clam fishery on the eastern shore.

Given the distinct possibility of overfishing, we think one of the best conservation measures with regard to blood clams is the cultivation of *A. ovalis*. It has a comparatively fast growth rate, should be relatively easy to spawn under hatchery conditions, and could be grown in conjunction with *M. mercenaria* on existing leases. We have anecdotal evidence that natural set of blood clams is sporadic and undependable, but hatcheries could provide a reliable source of seed. In addition, effective, feasible methods of floating culture (i.e., "Taylor floats") are already in use for hard clams on the eastern shore (Luckenbach and Taylor); similar use for *A. ovalis* would substantially reduce predation and enhance survival rates. If *A. ovalis* can be successfully cultured, this may augment or supplant the harvest of blood clams by other means and, possibly, lessen some of

the fishing pressure from them. Otherwise, the blood clam population on the eastern shore may decline rapidly over the next several years.

ACKNOWLEDGMENTS

This research was funded by the National Oceanic and Atmospheric Administration, National Marine Fisheries Service (NOAA Grant # NA46FD0339), and we thank Ms. G. Faye (NMFS/NOAA) for her helpful advice during the project. The NOAA Restoration Center provided funds for publication costs. We gratefully acknowledge the help and technical assistance of Radford University faculty, staff, and students, especially Dr. S. Dennis. We are indebted to Captain D. Bishop for his willingness to undertake the field survey and for providing valuable catch information, and to his wife, Elisa, for compiling and forwarding the information. We also thank Dr. M. Luckenbach, Ms. J. Watkinson, Ms. N. Lewis, Mr. R. Bonniwell, and Mr. R. Cashwell, and other technical staff of the College of William and Mary, Virginia Institute of Marine Sciences, Eastern Shore Laboratory, Wachapreague, VA for their hospitality and invaluable assistance during various portions of the project. Dr. G.H. Johnson, Department of Geology, College of William and Mary, graciously helped us with shell aging techniques, and Ms. G. Arnold, Virginia Institute of Marine Science, Glouster Point Laboratory, prepared a map of the study area. We also appreciate the helpful review comments and suggestions of Dr. C. Byerly, Dr. M. Carriker, Mr. J. Ewart, Dr. J. Kraeuter, Dr. C. Langdon, and anonymous reviewers.

A DIGITAL PRESENTATION OF THE MARYLAND OYSTER HABITAT AND ASSOCIATED BOTTOM TYPES IN THE CHESAPEAKE BAY (1974–1983)

G. F. SMITH, K. N. GREENHAWK, D. G. BRUCE, E. B. ROACH, AND S. J. JORDAN
Cooperative Oxford Laboratory, Maryland Department of Natural Resources, 904 S. Morris St., Oxford, Maryland 21654

ABSTRACT Between 1975 and 1983, the Maryland Department of Natural Resources conducted a survey of Maryland's portion of the Chesapeake Bay to reassess the extent and condition of oyster bottom (bars) that were initially surveyed in 1912. A variety of methods were employed to assess bottom condition, including bottom grabs, sounding poles, and dragged microphones. The survey used six categories to describe substrate type. Three of these represented oyster bottom: cultch (exposed oyster shell), cultch with sand, and cultch with mud. The other three categories were non-oyster bottom: sand, mud, and consolidated hard sediment. Bottom characterizations were drawn on 37 transparent *Mylar* sheets. Although the resulting charts were used to generate new legal oyster bar boundaries, the original bottom characterizations were never published. We present here the digitized *Mylars* in a Geographic Information System (GIS) polygon format, which is now available as a digital file. A comparison of results with more recent habitat assessments indicate the survey was a generally valid representation of the true bottom condition. The digitized survey results, however, could be misapplied if used as an exact description of current bottom conditions, because in many areas, cultch categories are actually shell covered by varying depths of sediment. This work provides a demonstration of how GIS-based analysis can be employed to interpret historical surveys of oyster habitats and provide a useful management product to resource managers.

KEY WORDS: oyster, habitat, Chesapeake Bay, GIS, cultch

INTRODUCTION

Fisheries management and ecological restoration of oyster habitat are generally obliged to rely upon old original bottom surveys, often over 100 years old. These surveys covered broad areas but relied upon crude methods. In the Chesapeake Bay, which lies within the boundaries of Maryland and Virginia, broad scale maps of oyster (*Crassostrea virginica*) habitat were constructed in the late 19th and early 20th centuries. In Virginia, oyster habitat was mapped by Baylor (1894). The first official survey of Maryland oyster bars was referred to as the Yates survey. Completed in 1911 (Yates 1911, Smith 1997), it was authorized in 1906 (Kennedy & Breisch 1983) to delineate oyster bottom to be reserved for public oyster harvest. A dragged chain was employed as the principal sampling method for the survey. The survey was in response to declining oyster harvest which went from 686,700 m^3 of live oysters in the shell in 1884 to 201,432 m^3 in 1906, despite increased harvest effort (Graves 1912). In the years following the Yates survey, much bay bottom was added to the public oyster ground by judicial decree. By the 1970s, there was increasing opinion that much of the original Yates-designated public bottom had become unproductive and should no longer be reserved exclusively for harvesting of oysters from public beds. Alternative uses were proposed for the public bottom, which by 1974, produced only 128,184 m^3 (MD-DNR 1989) of oysters annually (8,294 metric tons, NMFS 2000). Fishers interested in harvesting soft clams (*Mya areneria*), in particular, called for a re-examination of the original survey to determine which areas were still productive public oyster beds, which areas could be designated for clamming, and which could be available for private oyster leases. In 1974, the Maryland State Legislature authorized the Maryland Bay Bottom Survey (MBBS). The original mandate for the survey was to delineate the natural oyster bars of the State, the soft clam areas of the State, and what will be termed barren bottoms of the State, which could be leased to private individuals for oyster culture or other aquaculture purposes.

The challenges presented by the need to map oyster habitat and track historical changes are formidable. In Maryland, survey methods have varied greatly since the Yates Survey. The MBBS employed a combination of mechanical grab samples and hydroacoustic techniques to classify bottom types. The output from the MBBS were bottom-type renditions, represented as polygons, drawn on a series of transparent *Mylar* sheets. Each transparency matched the scale of one of the 37 official State of Maryland Natural Oyster Bar (NOB) charts (MD-DNR 1983) that depicted the boundaries of Maryland's public oyster bars. Although they were drawn at the scale of Maryland oyster bar charts, no reference information, such as latitude and longitude or shoreline, was depicted on the sheets. As such, they were extremely difficult to utilize in their original format. Because these renditions were not geographically referenced, and because they were gross simplifications of the information generated in the survey, they fell short of providing a comprehensive tool to manage the resource and track historical change. Instead, the principal use of the MBBS transparencies was to produce new legal oyster bar boundaries. In conjunction with the older Yates survey, the primary criteria for designation of new oyster bar boundaries was the distribution of cultch (exposed oyster shell)-bearing bottom. Because of the physical complexity of the bay bottom, new legal oyster bar boundaries were negotiated gross simplifications of bottom depicted by the MBBS. The first of the new NOB boundaries became effective in 1982. After serving as a basis for the generation of new official NOBs, the 37 *Mylar* sheets depicting the MBBS were archived.

In 1994, the Chesapeake Bay Stock Assessment Committee provided funding to digitize the original MBBS data into a GIS format for future public dissemination. GIS technology allows these data to be integrated with other spatially related datasets, such as bathymetry, for purposes of resource assessment. This paper was prepared in association with the introduction of the MBBS digitized dataset to the public. Because no detailed and integrated documentation of this survey was ever prepared, this review serves as a description and analysis of survey methods and results. In an effort to track historical changes in the oyster re-

source and habitat, and to provide for more effective management and restoration activities, it can be seen from this effort that there is a need to develop quantitative tools for comparing historical and current or future surveys of oyster habitat. From this process, we have identified approaches to applying quantitative Geographic Information System (GIS) analysis and display to plan for new approaches to oyster habitat mapping.

METHODS

Survey Overview

The survey began in 1975 and was expected to require approximately 3 years to complete. The original objectives stated that the entire Maryland area of the Chesapeake Bay would be surveyed, a departure from the original Yates Maryland oyster bar survey (Fig.1), where local "experts" identified potential oyster bottom for survey (Graves 1912). Because of the slow pace of work, the scope of the survey was later changed to assess only bottoms within and adjacent to the public bars identified by the Yates survey.

Navigation was principally by Raydist radio receivers (Teledyne Hastings, Hampton, VA.) Transmitting stations were established especially for the MBBS, and Raydist control sheets were prepared for boat use by overprinting existing natural oyster bar charts with overlapping hyperbolic Raydist lanes. For most sampling cruises, tracks directly followed Raydist lanes, thus transect bearings varied throughout regions of the bay. Sextant triangulation was used when electronic navigation failed.

Bottom sampling methods varied throughout the survey and included combinations of patent tong grabs (Chai et al. 1992), sounding poles, echo sounder tracings, and sounds from a dragged microphone. Patent tongs are a commercial oyster harvest device employing toothed jaws and a steel-framed enclosure capable of retaining oysters of commercial size. Patent tongs collected material from 1 m^2 surface area. Individual sample depth was variable depending upon substrate composition. It is estimated that approximately 15% of the survey was conducted with patent tongs, 10% with sounding poles, and the remaining 75% with microphones. Table 1 provides phases of the survey in which particular sampling methodologies were employed. Maximum MBBS survey depth was about 9 m because of limitations of patent tong sampling; boat draft limited minimum surveying depth to about 2 m.

All field surveying, with the exception of the Potomac River,

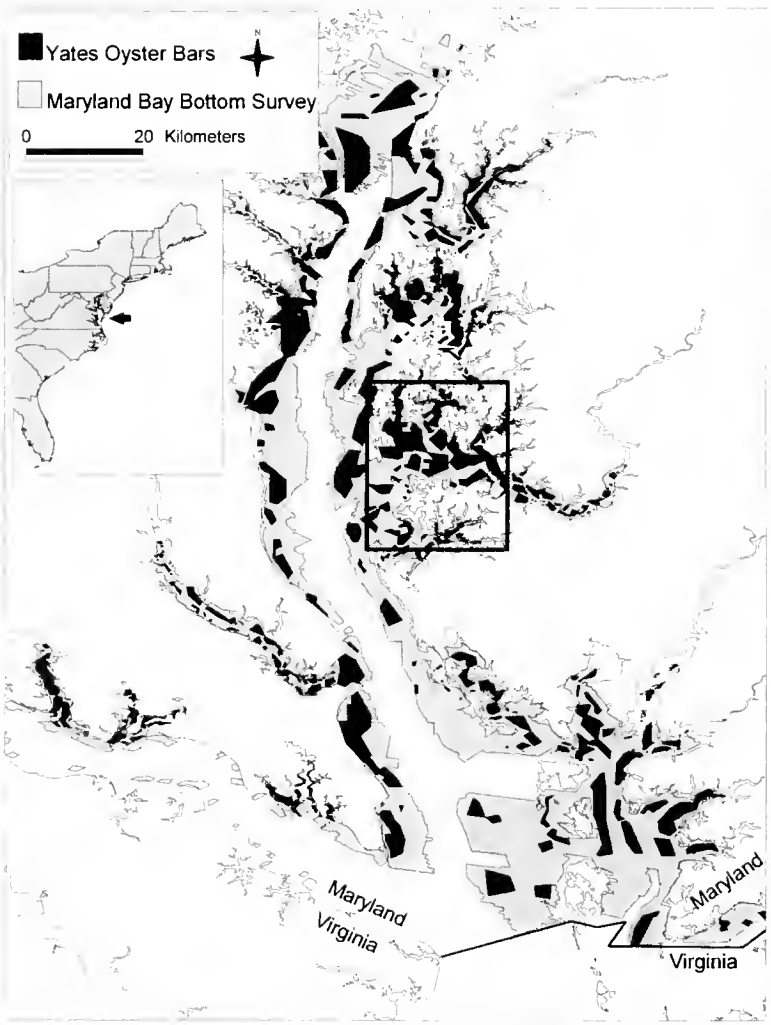

Figure 1. Comparison of the area covered by the original Yates oyster bars (black) to the region of the Chesapeake Bay covered by the Maryland Bay Bottom Survey (gray). Yates bars were surveyed in 1911 to delineate grounds for public oyster harvest. The boxed region is the lower Choptank River represented in Figure 2.

TABLE 1.

A chronology of sampling methods used by Maryland Bay Bottom Survey[a].

Method	Transect lane spacing	Station spacing along lanes	Data collected	Estimated km[b] sampled/day
Phase I–early 1975 to late 1976 Patent tongs (1 m^2), bottom profiling recording fathometer, and sounding poles	137–183 m	137–183 m	Bottom type and presence of benthic organisms	1.42
Phase II–late 1976 to early 1977 Recording fathometer only[b]	137–183 m	137–183 m	Three bottom types: hard, soft, unknown	2.02
Phase III–summer 1978 to late 1979 Dragged microphone[c] with shipboard transcription, recording fathometer, and sounding poles	183 m	183 m	Seven bottom types: sand, mud, shell/sand, shell/mud, shell, clay, and gravel	1.62
Phase IV–February 1980 to May 1980 Dragged microphone recorded shipboard with transcription on shore	183 m	Continuous	Six bottom types: sand, mud, shell/sand, shell/mud, shell, hard bottom	11.33
Phase V–June 1980 to November 1983 Dragged microphone analog output recorded on fathometer paper trace	183 m	Continuous	Six bottom types: sand, mud, shell/sand, shell/mud, shell, hard bottom	11.33

[a] Adapted from an anonymous and undated table titled "History of B.B.S. in Maryland" found in Maryland Department of Natural Resources files.
[b] Survey speed was to be increased by eliminating surveying in "nonproductive areas" and to use echo-sounding as an "exploratory/sample investigation." It was hoped that rapid preliminary reconnaissance with the bottom sounder and sounding pole could identify cultchless substrate that would not require exhaustive patent tong sampling. Reconnaissance data were apparently used as a basis to focus where more exhaustive sampling would be employed at a later date.
[c] This instrument was a waterproofed microphone dragged along the bottom that transmitted sound to an amplifier and speaker on the survey boat. Although specifications for the exact design are not available, the configuration described by Haven et al. (1979) would have operated in a similar fashion. Event marks were placed in the location record where there were marked changes in the sound produced.

was completed by October 1982. Survey of the Potomac began in July 1983 and was completed in November of 1983. This portion of the survey was conducted independently of the MBBS, because the Potomac River fishery is jointly managed by the States of Virginia and Maryland. Oyster bars on both shores of the river were surveyed, but oyster bars in Virginia tributaries were not charted. Preparation of bottom charts continued until the end of 1983.

The total area surveyed by the MBBS was 2591.9 km^2 and covered 42% of the Maryland portion of the Chesapeake Bay. A total of 7,543 polygon objects were used to depict bottom type (Fig. 2). Of the total area surveyed, 1,858 km^2 was outside of the original charted Yates bars. In the total survey, 477.7 km^2 of bottom was cultch, 201.9 km^2 sand with cultch, and 205.2 km^2 mud with cultch (Table 2). The GIS generated results included 0.575 km^2 of designated leased bottom, an attribute characterization for which habitat classification is not available.

TABLE 2.

Summary of bottom-type polygons digitized from original Maryland Bay Bottom Survey Charts.

Bottom type	No. polygons	Area (km^2)
Sand and shell	1,999	201.9
Shell	1,958	477.7
Sand	1,177	838.5
Mud and shell	1,155	205.2
Mud	845	733.4
Hard bottom	409	135.2
Total	7543	2591.9

Digitization

We digitized MBBS *Mylar* charts individually with MapInfo® software and then merged them into one datafile. The MapInfo projection and datum used was Longitude/Latitude (NAD27). Twelve to 15 control points were used to register the map to Earth coordinates. Coordinates of control points were georeferenced by overlaying the MBBS *Mylar* over the corresponding Maryland Natural Oyster Bar chart that had a graticule of latitude and longitude. Control point error values were all less than 0.05 cm root mean square in true chart dimension. Bottom type on MBBS mylars was represented as inked shapes, shaded to depict six discrete bottom categories. These categories were: cultch, sand with cultch, mud with cultch, sand, mud, and consolidated "hard" sediment (believed to be clay). Hand-drawn, smooth-sided delineations on the *Mylar* sheets were transformed to straight-sided polygons in the digitization process. We attempted to duplicate the original curved-sided objects as closely as possible by utilizing enough segment nodes to make the straight-sided polygons appear curved at normal magnifications of the GIS image (Fig. 2). Final data cleaning was performed to identify sliver polygons where two objects overlapped. This and other cleaning procedures were performed in ArcInfo® utilizing the "build" and "clean" functions.

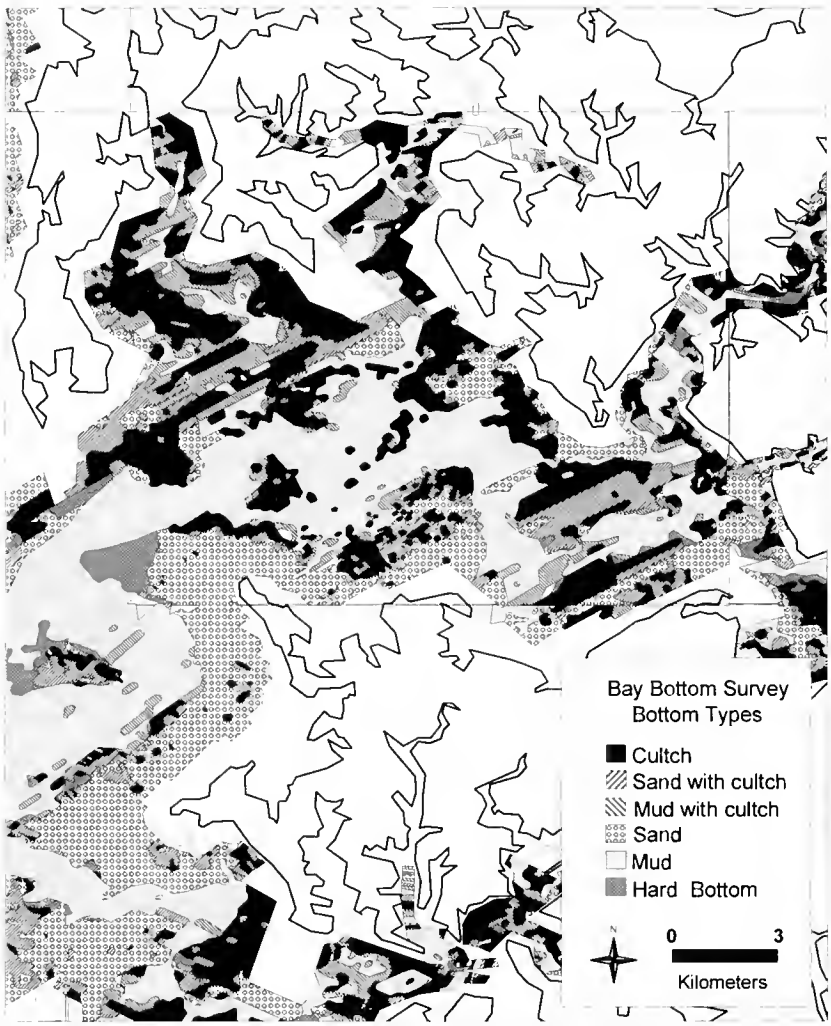

Figure 2. An example of the digitized rendition of the Maryland Bay Bottom Survey in the Choptank River region. The shoreline and the borders of the original *Mylar* charts are layered upon the survey bottom themes, but are not included in the digital file. Original *Mylar* transparencies were 70 × 111 cm, drawn at a scale of 1:20,000 and projected in U. S. State Plane NAD27. The general North–East / South–West orientation of bottom themes depicted here is the result of radio beacon navigation.

One of the original 37 *Mylars*, (southern East Bay) was missing from the set before digitization. Summary statistics do not include this lost *Mylar*, and the charted area it occupies in the digital dataset is empty.

Validation of Habitat Characterization

Comparative Analysis

To determine the relationship between categorical bottom types of the MBBS depictions and raw patent tong data from which they were generated, we obtained original field data from 1975 for two oyster bars, Cook's Point and Sandy Hill (Fig. 3), in the Choptank River. These oyster bar locations were chosen from a limited set of raw data still available from the original survey. We georeferenced and then superimposed this raw categorical bottom type data over the MBBS habitat depictions. Categorical bottom types identified on the patent tong datasheets included shell, sand and shell, mud and shell, sand, mud, mud and sand, stone, and clay. These are consistent with the MBBS bottom objects for these same locations.

In addition to categorical bottom type data, survey sheets gave the percentage of the patent tong sample by volume, which was cultch. To validate further how final survey bottom classification were made, we evaluated the association between cultch quantity in patent tong samples and MBBS habitat categories present at the two oyster bars. Data for individual samples from both bars were pooled, and a square root transformation on cultch percentages was performed after an evaluation of residuals. Data were subjected to a one-way analysis of variance (ANOVA), with bottom type as the experimental variable and percentage cultch as the response variable ($\alpha = 0.05$). A Tukey's mean comparison test (HSD) was then performed at $\alpha = 0.05$.

We also compared 1975 MBBS patent tong samples from Sandy Hill and Cook's Point to unpublished (M. Homer pers. comm.) 1993 patent tong samples obtained from the same bars by the Maryland DNR Oyster Stock Assessment Program (OSAP). Unlike MBBS datasets, OSAP sampling was uniform and complete within the entire Yates bar boundary. OSAP data were recorded as the number of liters of surface shell in each sample; whereas MBBS data were recorded as the percentage of shell in each sample. Because the two sampling methods were not in comparable units, nor convertible, cultch densities for both percentage

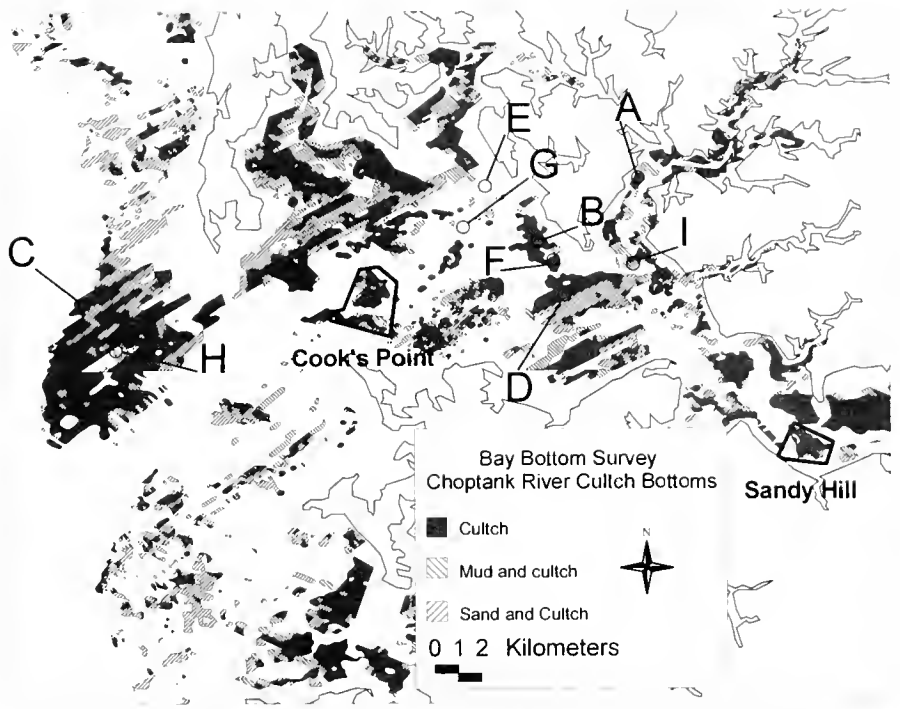

Figure 3. Selected diver observation and sediment analysis sites located on Maryland Bay Bottom Survey cultch designated bottoms in the Choptank River. Results of bottom analyses from sites A–H are presented in Table 3. Yates bar boundaries outline Cook's Point and Sandy Hill oyster bars.

of sample and liters per sample were each standardized to frequency distributions with a mean of 0 and an SD of 1.

Patent tong data from OSAP sampling at Cook's Point and Sandy Hill were also used to validate the shape of MBBS cultch objects. We created a continuous surface from OSAP data by importing point datafiles into an ArcInfo grid cell model. Cultch density patterns in the grid were then compared to the shape of cultch objects in the MBBS.

We used SCUBA dives in 1998 to perform qualitative assessment of the abundance of surface shell, and subsurface composition by probing with a diver knife, at nine locations designated as cultch in the MBBS (Fig. 3). At each site, SCUBA divers also collected one to three two-liter sediment samples to a depth of 15 cm. Samples were weighed and then sieved through 33-mm, 10-mm, and 5-mm mesh to determine percentage of shell by weight in each sample and the composition of nonshell material. Material passing through the 5-mm mesh was then subjected to traditional grain size analysis down to 16 μm (ASTM 1990).

An underwater benthic sled with color and B/W cameras was towed across the nine locations from where we collected the sediment samples. The direction of the video observation was variable, largely based upon wind and current condition. But, the exact path traversed was logged directly on the video tape by differential GPS signal.

Sub-Bottom Profiling

We used acoustic sub-bottom profiling systems to determine the relationship between MBBS cultch objects and Yates bar boundaries to oyster bar geomorphology. Transects were taken in January 1998 with an X-star® sub-bottom profiling system (Edgetech Inc., Milford, MA, USA) on and adjacent to Sandy Hill and Cook's Point oyster bars. Sub-bottom profiling output was a GPS logged gray-tone trace that identified bottom depth and the presence and depth of sub-bottom density discontinuities. Because output was GPS logged, we were able to associate profile features with MBBS objects.

RESULTS

Comparative Analysis

At Cook's Point and Sandy Hill oyster bars, only four of the six MBBS bottom classifications were recorded (Figs. 4a, b). Survey bottom polygon characterizations generally corresponded to raw patent tong bottom-type categorical data at Cook's Point and Sandy Hill bars. Seventy-eight percent of patent tong sample points were bounded by corresponding bottom type polygons at Cook's Point and 71% of points corresponding to like-bounding polygons at Sandy Hill. One apparent discrepancy in MBBS bottom characterization at Cook's Point was that patent tong datapoints characterized as sand with cultch or mud with cultch were depicted within bottom- type objects defined as cultch. Similar inconsistencies were found at the Sandy Hill site.

Mean percentage cultch varied significantly among the five categorical bottom types at the two sites. Tukey's mean comparison test indicated that mean percentage shell was significantly lower in the mud and sand bottom designations than in the cultch and sand, cultch and mud, and cultch categories (Fig. 5). Cultch density differences among the cultch, sand with cultch, and mud with cultch categories were not significant. These results indicate that the MBBS used qualitative assessment methods, and not strictly quantitative, to categorize cultch bottom types.

Analysis of OSAP data at Cook's Point and Sandy Hill provided little insight on the accuracy of MBBS bottom classifications and shapes of chart objects. Standardized cultch densities from the two surveys had differently shaped frequency distributions (Fig. 6). Cultch distributions at Cook's Point and Sandy Hill oyster bars

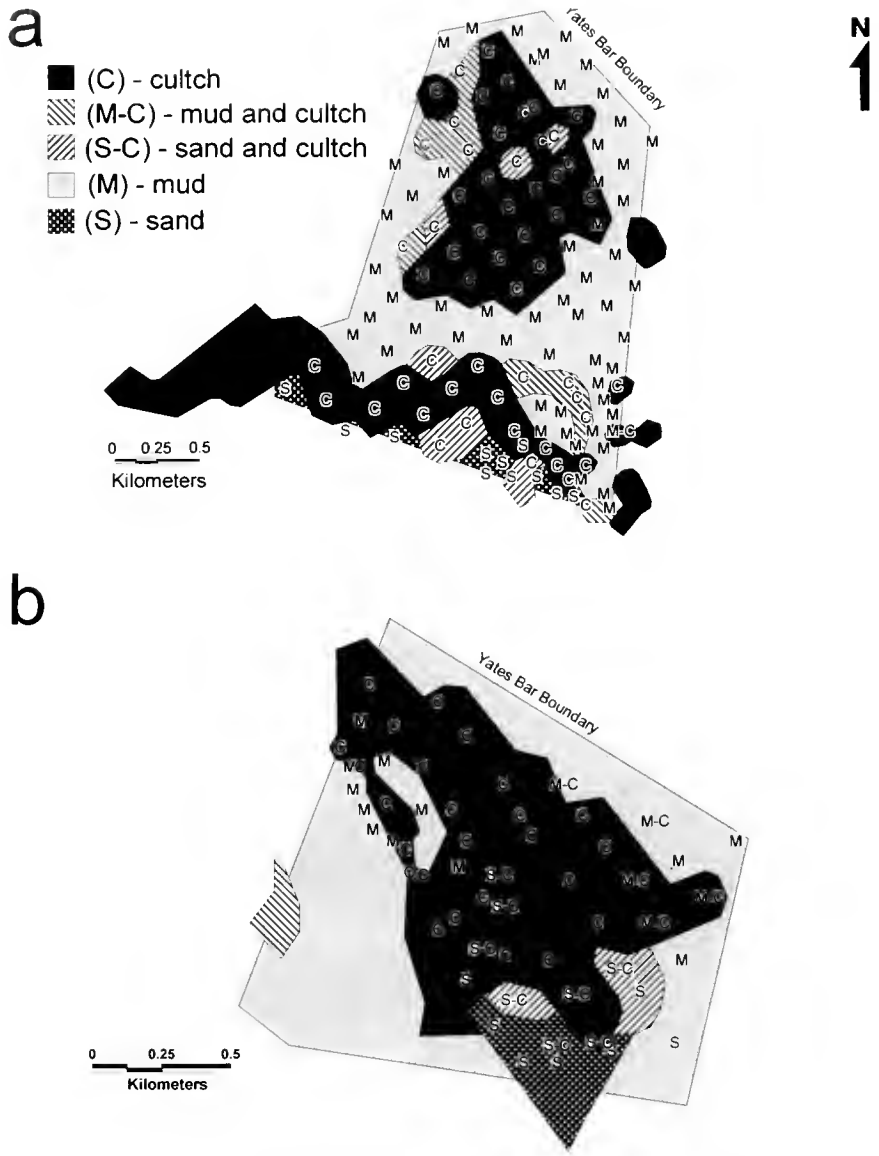

Figure 4. Relationships between patent tong point data and final bottom-type polygons of the Maryland Bay Bottom Survey. Point data are layered over bottom themes within Yates Bar boundaries at (a) Cook's Point and (b) Sandy Hill oyster bars. Characters represent substrate type: C = cultch, SC = sand and cultch, MC = mud and cultch, S = sand, and M = mud. Irregular spacing of datapoints within the Sandy Hill Yates bar boundary are attributable to lost data sheets.

from 1975 (MBBS) indicated a majority of low-density samples, with some high-density samples being present. Later 1993 (OSAP) data was highly skewed to low-density samples, with no high-density samples collected. Differences in shell density distributions indicate that either MBBS patent tong sampling was imprecise, relative to OSAP sampling, or that there has been a temporal decline in cultch density at the two oyster bars over the intervening two decades.

We did not observe any relationships between shell density patterns from OSAP grid cell models and the shape of MBBS cultch polygons. Multiple displays at various shell density levels used to depict cultch did not match MBBS cultch object shapes at either of the two oyster bars.

Results of diver observations, video footage, and sediment analysis at selected sites in the Choptank River indicate that much of the bottom described as cultch in the MBBS currently has little surface shell (Table 3). Divers, however, noted dense shell below surface sediments at all but one location. These results indicate that much of the bottom depicted as cultch in the MBBS is currently degraded by sedimentation or that some of the methods used in the MBBS were unable to discern sedimented shell from clean shell.

Sub-Bottom Profiling

We found that the physical perimeters of oyster bars generally occur at points where hard sub-bottom terraces emerge from surface layers of soft sediment or at main channel margins. These features are identified on sub-bottom profiles by acoustic density discontinuities or rapid bathymetric change. Borders of MBBS cultch objects and Yates bar boundaries at Cook's Point and at Sandy Hill generally coincide with these features (Fig. 7). In most cases MBBS cultch boundaries were more accurate in depicting

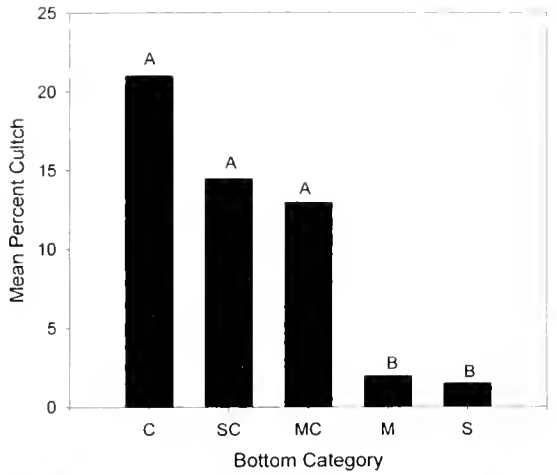

Figure 5. Mean percentage cultch from patent tong samples relative to corresponding bottom classifications. Patent tong data were pooled from collections made at Cook's Point and at Sandy Hill oyster bars. We used analysis of variance (ANOVA) and Tukey's multiple comparison test ($\alpha = 0.05$) on square root transformed data to assess the validity of categorical bottom designations. Mean percentage cultch at bottom types with the same letter were not significantly different. Bottom categories are: C = cultch, SC = sand and cultch, MC = mud and cultch, M = mud, S = sand.

true oyster bar margins than the original Yates bar charts. The generality of Yates bar boundaries results from the purpose of the survey, which was charting protected public oyster bottom rather than identifying bottom types.

DISCUSSION

The 1975 to 1983 Maryland Bay Bottom Survey was the first baywide assessment of oyster habitat since the early 1900s. The area of bottom covered was 342% larger than the portion of the bay designated as public oyster bar by the Yates survey of 1911. Unlike the Yates survey, the MBBS is a categorical description of bottom that is relevant to oyster ecology in addition to regulation of harvest. Our digital rendition of the MBBS survey increases the facility of analysis and display at local and regional scales. The digital format will also allow resource managers and interested parties to identify historic regions of oyster habitat and areas for rehabilitation. This dataset is available for distribution from the Cooperative Oxford Laboratory (Mapping and Analysis Project, Cooperative Oxford Laboratory, 904 S. Morris St., Oxford, MD 21654, (410) 226-0078).

An understanding of the strengths and weaknesses of the MBBS should precede any serious application of these data. Figure 7 is an example of how the MBBS may be a more accurate depiction of the true morphological character of oyster bars than the previous Yates survey. In many cases, the MBBS polygon boundaries corresponded to oyster bar edges identified by sub-bottom acoustic profiles; whereas, Yates bar boundaries provided a more generalized representation. Comparison between bottom category and percentage cultch indicated that bottom classifications, at least where patent tong sampling was employed, were systematically determined from cultch volume and that there was a relationship between MBBS bottom category and cultch density.

Little documented information exists about the methodology and consistency of the methods used to translate field data to the final six bottom classifications. The limited information available from raw patent tong data at Cook's Point and Sandy Hill oyster bars (Figs. 4a,b) showed a relationship of sample data to the derived objects, but there were some discrepancies. These inconsistencies suggested that additional information was incorporated into developing bottom classification. Patent tong field sheets from Cook's Point and Sandy Hill show that data were recorded for bottom type and percentage cultch for upper, middle, and lower strata within each patent tong sample. Although bottom type and percentage cultch were, in many cases, different between strata from the same sample, there was no consistent pattern indicating whether sub-surface information was used to generate final bottom categories.

The graphic representation of the MBBS was affected by data collection and translation procedures. A linear pattern of northeast–southwest orientation can be seen throughout the charts (Fig. 2). This is an artifact of transect orientation along radio beacon lines, and the width of these patterns provides the scale of transect spacing. Because each of the 37 *Mylar* sheets were drawn

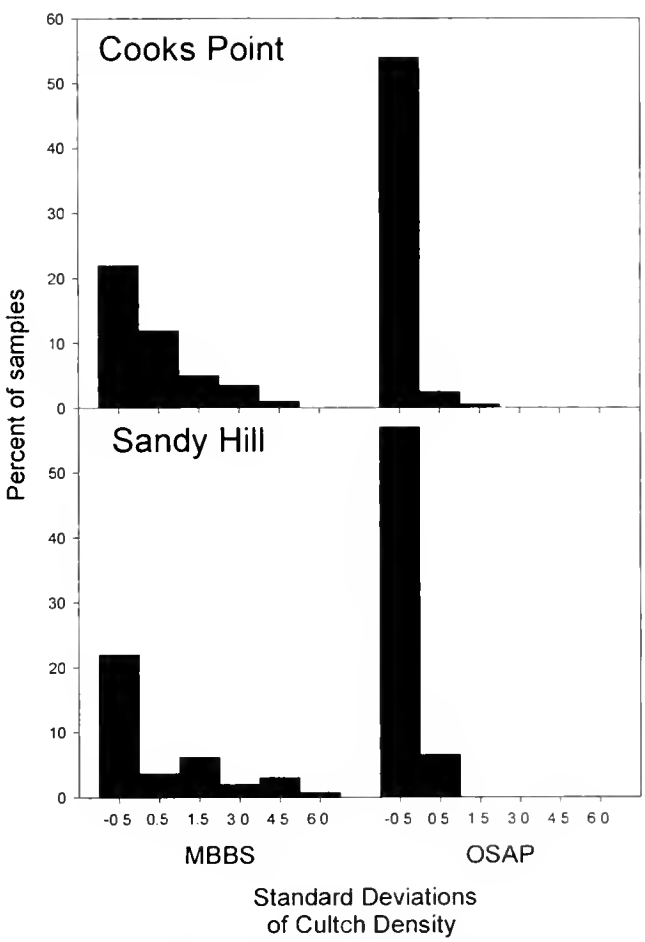

Figure 6. A comparison of cultch densities from 1975 patent tong samples recorded on Maryland Bay Bottom Survey (MBBS) field sheets to patent tong samples collected in 1993 at Cook's Point and Sandy Hill oyster bars. Recent patent tong samples were collected for the MD DNR Oyster Stock Assessment Program (OSAP) and were recorded as liters of shell per sample; whereas, MBBS data were recorded as percentage shell per sample. To compare absolute and relative units, both datasets were fit to standard frequency distributions with a mean of 0 and an SD of 1.

independently of each other, objects at chart edges did not merge precisely, and we were forced to adjust most junctures when we integrated individual charts into the final GIS data file (Fig. 2).

For some information requirements, the MBBS may not be a realistic depiction of the conditions of the Chesapeake Bay bottom in the 1970s and 1980s. Most bottom areas observed in the mesohaline portion of the bay are transitional, grading between the six generic categories of the MBBS. Intermediate bottom types often predominate over discrete bottom types, and many areas of the bottom, particularly where cultch is present, exhibit extreme heterogeneity. The categorical polygon data model used does not represent transitional areas, because it depicts an abrupt change between bottom types. Furthermore, depictions of bottom, are for the most part, characterizations assembled from sampling points along a transect line, thus fine scale heterogeneity is not adequately represented. Our diver and video observations on the bottom in the vicinity of Cook's Point and Sandy Hill oyster bars show extreme patchiness of cultch and sediment at centimeter and larger scales. An additional complication is that we do not know exactly what the "hard bottom" MBBS bottom habitat classifications means. The term "deep water" has been associated with it in some reference notes, although the survey did not extend into waters deeper than 9 m. Our visual observations in hard bottom areas often show a clay-like substrate.

Current Relevance

Most of the MBBS survey was conducted mainly with a dragged underwater microphone, and identification of cultch was generated by contact and abrasion on hard objects. Little information, however, is available to determine the accuracy of MBBS microphone data. Verification sampling via patent tong and diver observation to validate microphone acoustics was initiated toward the end of the survey, but results cannot be located. A principal source of error associated with the microphone method is that oyster shell is not the only hard substrate on the bottom. We have observed pebbles, cobbles, and occasionally boulders from video and diver observation in the Choptank River region. Some of these stony bottoms often include scattered or dense shell and were characterized as cultch in the survey. We know that the microphone distinguished smooth from rough bottom and could identify transition zones between the two. However, the presence and density of cultch may be confounded by other hard objects. The use of an underwater microphone for surveying was not novel. From 1978 to 1981 the public oyster grounds of the James River in Virginia were similarly surveyed (Haven et al. 1979, Haven & Whitcomb 1983), with data being reduced to six bottom characterizations identical to those later employed by the MBBS.

Acoustics were also employed in the mapping of Galveston Bay, Texas beginning in 1991 (Powell et al. 1995). In this case, dual frequency transceivers (27 and 300 kHz) were utilized to compare results to data collected in the 1970s by a manual polling technique. Polling was additionally employed as ground truthing during the recent survey. Principal oyster habitat distinctions employed were between hard consolidated reef and unconsolidated shell. GIS data generation were employed principally to generate polygon areas of these categories. Unlike the Maryland Bay Bottom Survey, wholesale habitat type mapping was not a component of the published results.

Our analysis of sediment samples, qualitative diver observations, and video footage, at areas characterized as cultch by the MBBS showed small amounts of surface cultch and an almost universal presence of shell beneath surficial sediments. Trace quantities of exposed cultch or no exposed cultch was the dominant surface character. This situation is true for almost the complete extent of the large MBBS cultch object depicted at the top of Cook's Point oyster bar (Fig. 7). Video transects over tens of meters did not yield any surface cultch. These observations seem to agree with results of the OSAP patent tong-sampling program from the early 1990s. From the OSAP data, we calculated a mean shell volume of $1.6 \times L \times m^{-3}$ from samples collected within all MBBS cultch, sand with cultch, and mud with cultch objects within Yates bar boundaries for the entire Choptank River region. When completely filled, patent tongs sample 52.0 lm^3 of substrate in each grab. The standardized rank comparisons in Figure 6 also indicate that much of the bottom depicted as cultch in the MBBS

TABLE 3.

Recent substrate examinations at sites identified as cultch bottom by the Maryland Bay Bottom Survey 1975–1983.

Site	Bottom category	Mean shell abundance (% by weight)	Qualitative visual estimates		
			Shell abundance (%)	Nonshell[a] substrate type	Subsurface composition
A	Cultch	7	0	4	Dense shell
B	Cultch	5[b]	50[b]	2,3,5,6,7	Shell/rock
C	Cultch	6	1	1,2,3,5,6,7	Shell/rock
D	Cultch	8	15	4,6	Dense shell
E	Cultch	9	1	3,4,7	Dense shell
F	Cultch	0	1	7	Light shell
G	Cultch	16	0	4	Dense shell
H	Sand/cultch	0	1	3,7	Dense shell
I	Mud/cultch	0	0	4	Mud

[a] Substrate codes: 1 = boulder, 2 = cobble, 3 = grit, 4 = mud, 5 = pebble, 6 = shell bits, 7 = sand.

[b] Difference in shell abundance due to extreme bottom heterogeneity at site.

Sites were selected to be representative of the widest variety of bottom types observed in the Choptank River estuary of the Chesapeake Bay. One to three replicate sediment samples were collected by divers at each site in summer of 1998. Shell abundance was measured as percentage by weight of shell >30 mm from 2 L samples taken to a depth of 15 cm. Visual estimates were recorded from qualitative diver observations of surface shell abundance, nonshell substrate composition, and subsurface composition determined from probing with a diver's knife. Site locations are depicted in Figure 3.

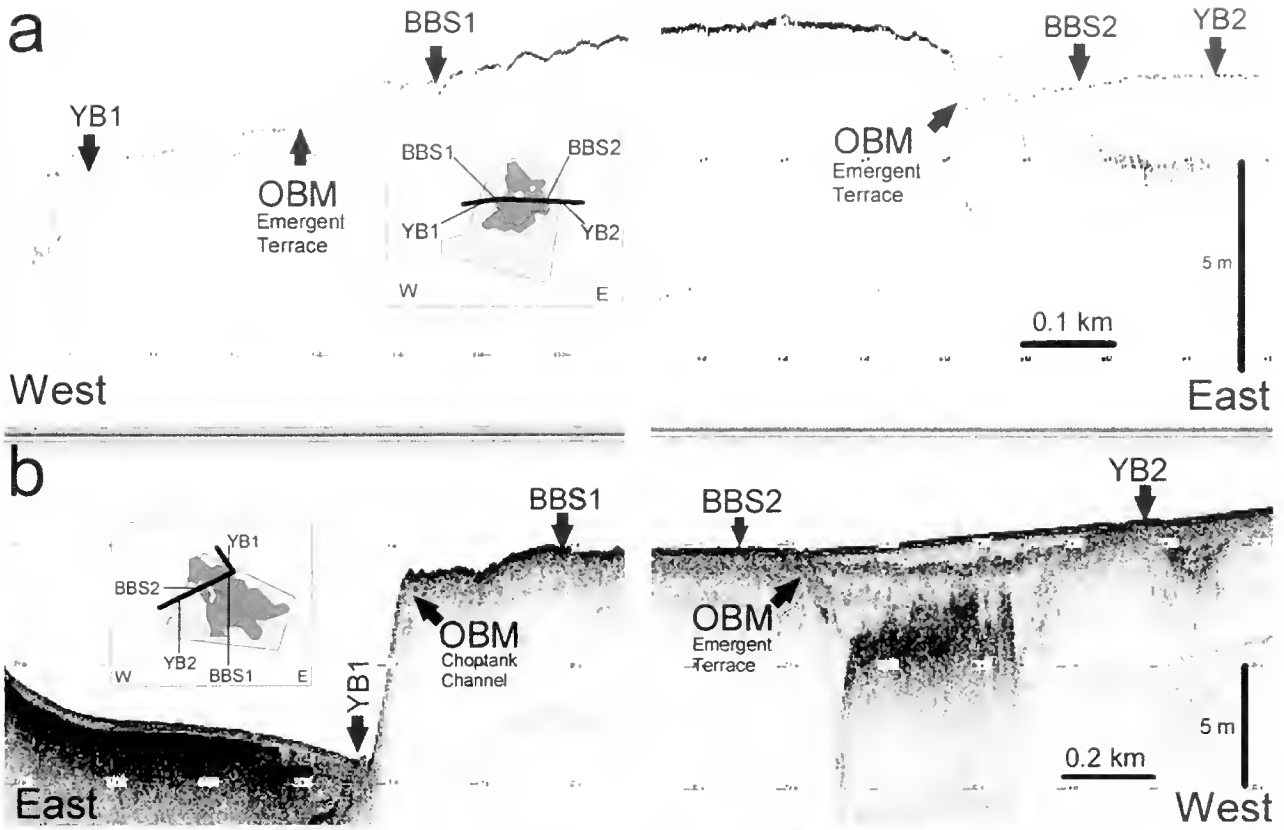

Figure 7. Acoustic sub-bottom profiles taken at Cook's Point (a) and Sandy Hill (b) oyster bars. Arrows indicate where boundaries of Maryland Bay Bottom Survey cultch objects (BBS1 and BBS2) and Yates bar perimeter boundaries (YB1 and YB2) intersect sub-bottom profiling transects. Inserts show where transects cross MBBS cultch objects and Yates bar boundaries. Actual oyster bar margins (OBM) occur where hard sub-bottom terraces emerge from soft bottoms or at the edges of existing channels. The western margin of Sandy Hill occurs at the edge of a sediment-filled paleochannel of a tributary of the Choptank River. The dark feature in the channel is the signature of gas-charged sediments.

is currently degraded by an overburden of sediment. We cannot determine whether this is a recent phenomenon or existed in the mid-1970s to 1980s when the MBBS survey was performed, and methods used by the MBBS may have been biased against detecting sediment on shell. Furthermore, the underwater microphone may have been unable to distinguish clean surface cultch from cultch covered by a layer of sediment. Also, sampling the bottom with patent tongs allows any overlying sediment to be washed from shell as the sample is brought up through the water column.

Caution must be used in how the results of the MBBS are applied. Comparison between the Yates survey and MBBS charts have been used to estimate temporal decline of oyster habitat (Rothschild et al. 1994). Although this study implicates that overharvest has an impact on the oyster habitat, comparative methods between the Yates boundaries and MBBS polygons did not include the MBBS bottom category mud with shell as oyster bottom. Aerial summations were only made with the shell and sand with shell categories, thus potentially greatly inflating habitat loss estimates (Table 3).

In addition, we have shown that Yates bar boundaries may provide coarser descriptions of the distribution of shell resources than the MBBS. This is because the Yates survey was intended to map legal boundaries of public oyster bottom and not necessarily shell distribution. MBBS cultch objects reveal the distribution of shell on the bottom, but say nothing about the quality of oyster habitat. Because oyster veligers require a clean surface for settlement, sediment-free shell is one of the most important components of quality oyster habitat (MacKenzie 1983). Patent tong and underwater microphone methods used to assess oyster habitat may also be unable to identify clean shell from that carrying a sediment load. To assess temporal changes in oyster habitat accurately, new methods must be developed to differentiate between clean shell and shell covered by an overburden of silt (Smith and Greenhawk 1998).

The digitization of survey results and GIS analysis of data has shown the value of GIS as a tool for the examination and analysis of benthic data. This complete dataset of over forty chart size *Mylars* can now be readily examined at ease on a computer screen in association with such related datasets as shoreline, bathymetry, and recent or planned sonar surveys.

Because of the recent integration of acoustic habitat assessment technology with extremely accurate satellite positioning information and GIS data capture and display, new possibilities are available to chart cost effectively and computer generate extensive bottom surveys. The cumbersome nature of data reduction performed in the MBBS generation can now be eliminated.

Benthic habitat charting via remote acoustic methods now provides three principal technological approaches for the assessment and representation of the bottom. Traditional single beam sonar can be used to assess general surface characteristics or sub-surface features. Habitat classification with such systems is still largely subjective. Side scan sonar technology can provide for strip-like textural images of the bottom that can now, by means of computer mosaicking, be seen as large, two-dimensional images. Although

often highly informative as to bottom character at a fine resolution, these side scan systems are still imaging reflectivity of sound only and often require extensive ground truthing. Finally, new technology referred to as Acoustic Seabed Classification Systems (ASCS) has been developed that statistically classifies acoustic echo returns by waveform characteristics into definable habitat types. With ASCS, rapid bottom classification can be made for each sonar ping transmitted. Because reflected acoustic waveforms carry a multitude of substrate information, it may not originally be known just what parameters of the substrate are being used in classification. As with other acoustic techniques, these systems require extensive ground truthing.

Despite technological advances, almost twenty years after its completion, the MBBS is still the best spatial depiction of over-all oyster habitat in the Maryland portion of the Chesapeake Bay. The scale and effort of the undertaking was so great that it will probably remain for some time as our best baseline information source on the distribution of shell resources. Despite weaknesses in documentation of methodology, and sediment overburden in areas described as cultch, we feel comfortable that the survey is a good guide to the location of areas most suitable for oyster bar restoration and a general guide to sediment composition in Maryland's portion of the Chesapeake Bay bottom.

DIFFERENTIAL DIAGNOSIS OF MIXED *HAPLOSPORIDIUM COSTALE* AND *HAPLOSPORIDIUM NELSONI* INFECTIONS IN THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*, USING DNA PROBES

NANCY A. STOKES AND EUGENE M. BURRESON*

Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, Virginia 23062

ABSTRACT *Haplosporidium costale* and *Haplosporidium nelsoni* are morphologically similar pathogens of the eastern oyster *Crassostrea virginica*. In the absence of the spore stage, infections of the two species are extremely difficult, if not impossible, to distinguish using traditional light microscopy of stained tissue sections. Species-specific molecular diagnostics were developed for *H. costale* from the small subunit ribosomal DNA (SSU rDNA) sequence. The polymerase chain reaction (PCR) primers amplified a 557 base pair (bp) region of the *H. costale* SSU rDNA, but did not amplify DNA from oyster (*C. virginica*) or from six other haplosporidans (*H. nelsoni*, *H. louisiana*, *H. lusitanicum*, *Minchinia teredinis*, *M. chitonis*, or *M. tapetis*). The DNA probe was used with *in situ* hybridizations of oyster tissue sections to visualize *H. costale* plasmodia and prespore stages; it did not hybridize with oyster (*C. virginica*) or other haplosporidans (*H. nelsoni*, *H. louisiana*, or *Minchinia teredinis*). DNA-based diagnostics for *H. costale*, in conjunction with molecular tools previously developed for *H. nelsoni*, have overcome limitations of histological examination. From *in situ* hybridizations using both probes, some Virginia oysters previously diagnosed with *H. costale* were found to have mixed infections consisting of approximately 80 to 90% *H. costale* plasmodia and 10 to 20% *H. nelsoni* plasmodia. Plasmodia of *H. costale* were not found in epithelial tissue, only in connective tissue. In addition, use of the DNA probe confirmed the presence of *H. costale* plasmodia in Virginia oysters collected in the fall, an unprecedented seasonality for an advanced *H. costale* infection.

KEY WORDS: *in situ* hybridization, small subunit ribosomal DNA, *Haplosporidium nelsoni*, *Haplosporidium costale*, eastern oyster, *Crassostrea virginica*, parasites

INTRODUCTION

Haplosporidium nelsoni Haskin, Stauber, and Mackin (MSX disease) and *Haplosporidium costale* Wood and Andrews (SSO disease) are morphologically similar pathogens of the eastern oyster, *Crassostrea virginica* Gmelin, that occur along the East Coast of the United States. *Haplosporidium costale* is generally thought to be restricted to high salinity bays (>25 ppt) along the open coast from Virginia to Maine; it is rare in the Delaware Bay and in the Chesapeake Bay (Andrews & Castagna 1978; Andrews 1988). *Haplosporidium nelsoni* occurs from Florida to Maine in both estuarine and oceanic habitats where the salinity is greater than about 10 ppt (Haskin & Andrews 1988). Thus, the distribution of the two pathogens overlaps in high salinity areas from Virginia to Maine.

If spores are present the parasites are easy to distinguish because *H. nelsoni* sporulates only in the epithelium of the digestive diverticula, whereas *H. costale* sporulates throughout the connective tissue of most organs (Couch 1967, Andrews & Castagna 1978). Moreover, spores of *H. nelsoni* are about twice the size of *H. costale* spores (Couch 1967). However, in the absence of spores, differentiation of the two parasites is very difficult, if not impossible. According to Couch (1967) plasmodia stages of both *H. nelsoni* and *H. costale* occur in epithelial and connective tissues in both mixed and single infections, so location of plasmodia is not helpful. *Haplosporidium costale* has a very restricted seasonality, with plasmodia present from March through June and spore stages present during May and June (Andrews et al. 1962, Andrews & Castagna 1978). However, plasmodia stages of *H. nelsoni* may also be common during the spring (Andrews 1982). Morphology of plasmodia has apparently been used to distinguish the species, with some difficulty. Couch and Rosenfield (1968) conducted a comparative study of *H. costale* and *H. nelsoni* in Chincoteague Bay, Virginia. They state that diagnoses of the two parasites in living oysters was based on recognition of the plasmodium, but they do not give any criteria used to distinguish the plasmodia of the two species. Mixed infections of *H. nelsoni* and *H. costale* were observed during the same study (Couch 1967), but they were based on the presence of spores of both species. However, criteria for distinguishing plasmodia of *H. nelsoni* and *H. costale* were provided (Couch 1967). They included: nuclear membranes of *H. costale* usually not as sharply defined or distinct as those of *H. nelsoni* and nucleoli (endosomes) of *H. costale* nuclei proportionately larger, less distinct, more diffuse, and more central than nucleoli of *H. nelsoni*. Andrews and Castagna (1978) stated that all stages of *H. costale* average smaller than those of *H. nelsoni*, but they went on to say that no definitive characters have been found with Harris hematoxylin and eosin (HHE) stain to distinguish *H. costale* and *H. nelsoni* plasmodia.

The specificity of molecular diagnostic tools, especially DNA probes used in *in situ* hybridizations, make them ideal for distinguishing morphologically similar species. Such tools are invaluable in elucidating certain ecological aspects of parasites that are difficult using traditional techniques (Burreson et al. 2000). Molecular diagnostic tools have been developed for *H. nelsoni* (Stokes & Burreson 1995, Stokes et al. 1995a). Specific polymerase chain reaction (PCR) primers have been developed for *H. costale* (Ko et al. 1995), but a DNA probe for that species has not been developed. Here we develop molecular diagnostic tools for *H. costale* and use the DNA probe in conjunction with an *H. nelsoni* DNA probe to identify mixed plasmodial infections of the two species. In addition, the molecular tools provided unexpected new information on the seasonality of *H. costale* in Virginia.

MATERIALS AND METHODS

DNA Sequences and Oligonucleotide Synthesis

The SSU rDNA sequences of *H. costale*, *H. nelsoni*, and *C. virginica* (GenBank accession AF387122, U19538, and X60315,

*Corresponding author.

respectively) were aligned using the MacVector software package (Oxford Molecular Group) and regions unique to *H. costale* were identified. PCR primers SSO-A (5′-CACGACTTTGGCAGTTAGTTTTG-3′) and SSO-B (5′-CGAACAAGCGCTAGCAGTACAT-3′) and DNA probe SSO1318 (same sequence as SSO-B, 5′ end labeled with digoxigenin) were commercially synthesized (Genosys Biotechnologies).

PCR Amplification

PCR reaction mixtures contained reaction buffer (10 mM Tris, pH 8.3; 50 mM KCl; 1.5 mM MgCl; 10 μg/mL gelatin), 400 μg/mL bovine serum albumin, 25 pmoles each of SSO-A and SSO-B, 200 μM each of dATP, dCTP, dGTP, dTTP, 0.6 units AmpliTaq DNA polymerase (Perkin–Elmer), and template DNA in a total volume of 25 μL. The reaction mixtures were cycled in a GeneAmp PCR System 9600 thermal cycler (Perkin–Elmer) 35 times at 94°C for 30 sec, 59°C for 30 sec, and 72°C for 1.5 min with a final extension at 72°C for 5 min. PCR reaction mixtures and cycling conditions for *H. nelsoni* were identical, except the primers were MSX-A′ and MSX-B (Renault et al. 2000, Stokes et al. 1995a). An aliquot (10% of reaction volume) of each PCR reaction was checked for amplification product(s) by agarose gel electrophoresis and ethidium bromide staining.

PCR Specificity and Sensitivity

Primer specificity was tested in PCR reactions using cloned SSU rDNA from *H. costale*, *H. nelsoni*, *Haplosporidium louisiana* Sprague, and *Minchinia teredinis* Hillman, Ford, and Haskin, and genomic DNA from *Haplosporidium lusitanicum* Azevedo, *Minchinia chitonis* (Lankester), *Minchinia tapetis* (Vilela), and uninfected *C. virginica*. Preparation of the cloned SSU rDNAs were described previously (Stokes et al. 1995a). Hatchery-reared juvenile *C. virginica* were collected in July 1999, and genomic DNA was tested for the presence of *H. nelsoni* by PCR, as described previously (Stokes et al. 1995a). Limpets, *Helcion pellucidus*, were collected from Cap de La Hague, near Cherbourg, France in September 1998 and screened for the presence of *H. lusitanicum* spores. Chitons, *Lepidochitona cinereus*, were collected from Wembury Bay, near Plymouth, England in September 1996 and screened for the presence of *M. chitonis* spores. *Minchinia tapetis*-infected clams, *Ruditapes decussatus* (L.), collected from Vilalonga in the Ria de Arousa, Galicia, Spain, in 1997 were kindly supplied by Antonio Villalba. Spores were concentrated from infected tissues and DNA extractions from spores and from *C. virginica* were performed with mechanical grinding followed by detergent lysis, as described previously (Stokes et al. 1995b). Primer sensitivity to homologous target DNA was determined with ten-fold serial dilutions from 100 pg to 1 fg of cloned *H. costale* SSU rDNA.

Histology

Tissue samples were preserved in Davidson's AFA for at least 24 h. Fixed tissues were embedded in paraffin, sectioned 5–6-μm thick, and placed on positively charged slides (Fisher Scientific) for *in situ* hybridization or hematoxylin and eosin (H&E) staining. Tissue sections were kept in order as they were cut, and the consecutive sections were numbered on the slides. The microtome blade and forceps were cleaned with xylene between samples to prevent carry-over DNA contamination.

In Situ *Hybridization (ISH)*

Tissue sections for ISH were processed as described previously (Stokes & Burreson 1995), except hybridization solution contained 5 ng/μL SSO1318 DNA probe or 2 ng/μL MSX1347 DNA probe and the addition of Bismarck Brown Y counterstain after the nitroblue tetrazolium and 5-bromo-4-chloro-3-indoyl phosphate (BCIP) color development. Slides were washed with TE buffer (10mM Tris, pH 8.0; 1mM EDTA), then with dH_20 to stop the NBT/BCIP color development. Tissue sections were stained with 1% Bismarck Brown Y (Sigma Chemical) for 1 min, then rinsed three times with dH_20. The slides were coverslipped with GVA Mounting Solution (Zymed Laboratories) and examined by light microscopy. Negative control ISH consisted of dH_20 instead of DNA probe in the hybridization solution. Consecutive tissue sections of all samples were processed in the following order: section 1, stained with H&E; section 2, ISH with SSO1318; section 3, ISH with MSX1347, section 4, ISH with no probe.

DNA Probe Specificity

In situ hybridization with both DNA probes SSO1318 and MSX1347 were performed on four *C. virginica* that had been diagnosed by histological examination as infected only with *H. costale* (Table 1). The Virginia Marine Resources Commission (VIMS) Oyster Disease Archive reference numbers for these oysters, embedded in paraffin, are 177,822, 181,676, 181,677, and 196,774. All of these oysters were collected at Wachapreague, VA, on the sea side of Virginia's Eastern Shore, the type locality (Wood and Andrews 1962) for *H. costale*. To demonstrate the

TABLE 1.

Samples tested with in situ hybridizations using DNA probes SSO1318 and MSX1347.

Archive Sample Number	Collection Date	Diagnosis by Histological Examination	Diagnosis by *in situ* Hybridization
177,822	May 1988	*H. costale* heavy (spores present)	*H. costale* heavy; *H. nelsoni* heavy
181,676	May 1989	*H. costale* heavy (spores present)	*H. costale* heavy
181,677	May 1989	*H. costale* heavy (spores present)	*H. costale* heavy; *H. nelsoni* rare
196,774	October 1994	tentative *H. costale* heavy*	*H. costale* heavy; *H. nelsoni* light

* Diagnosis of 196,774 was uncertain. The infective agent appeared to be *H. costale*, however, such seasonality of an advanced infection was unprecedented.

Histological examination column indicates parasites identified in tissue sections and infection levels of original diagnoses. In situ hybridization column indicates parasites identified in tissue sections and infection levels with DNA probes. All samples were collected from the vicinity of Wachapreague, Virginia.

specificity of probe SSO1318, ISH was performed on sections of *C. virginica* tissues infected with *H. nelsoni* and *Perkinsus marinus* (Mackin, Owen, and Collier), of shipworm (*Teredo* sp.) tissue infected with *M. teredinis*, and of mud crab (*Panopeus* sp.) tissue infected with *H. louisiana*.

RESULTS

Specificity and Sensitivity of PCR Primers

The *H. costale* PCR primer pair SSO-A and SSO-B amplified a 557 bp region of the *H. costale* small subunit rDNA (Fig. 1A), targeting bases 784 to 1340 of that gene. The primers did not amplify DNA from oyster or from the haplosporidans *H. nelsoni*, *H. louisiana*, *H. lusitanicum*, *M. teredinis*, *M. chitonis*, or *M. tapetis* (Fig. 1A). The PCR product was readily detected after amplification of 100 fg to 100 pg of cloned *H. costale* SSU rDNA; 10 fg of template DNA was amplified, but the product band was very faint in the agarose gel (Fig. 1B).

Specificity of DNA Probe

One of the candidate *H. costale* probes, designated SSO1318, was found to be sensitive and specific for *H. costale* in *in situ* hybridizations of tissue sections. Optimal hybridization required 5 ng/μL SSO1318 and incubation at 42°C. The SSO probe readily detected *H. costale* plasmodia and immature spores in sporocysts in ISH of oyster tissue with virtually no background, as indicated by the cells that stained dark purple to black (Fig. 2). DNA probe SSO1318 did not hybridize with oyster tissue (*C. virginica*), the oyster pathogen *P. marinus*, or the haplosporidans *H. nelsoni*, *H. louisiana*, and *Minchinia teredinis* (Fig. 3).

Differential Diagnosis using DNA Probes

Four oysters previously diagnosed by routine histological examination of H&E-stained paraffin sections as infected with *H. costale*, but not *H. nelsoni* (Table 1) were subjected to ISH using separate DNA probes for *H. costale* and *H. nelsoni*. Plasmodia and immature spores in tissues of all four oysters hybridized with the SSO probe (Figs. 4–6), thus supporting the histological diagnoses. However, some plasmodia in three of the four oysters did not hybridize with the *H. costale* probe, but instead hybridized with the *H. nelsoni* probe (Figs. 4–6). These mixed infections of *H. costale* and *H. nelsoni* were not distinguishable nor detectable by histological examination in part because only plasmodial stages of *H. nelsoni* were present, but they were readily apparent by *in situ* hybridization (ISH) using the species-specific DNA probes. Even a light infection of *H. nelsoni* plasmodia, scattered among a heavy infection of *H. costale* was easily detected using a DNA probe (Fig. 4E). In addition, the *H. costale* probe enabled discrimination of early and maturing plasmodia, the latter, which have vacuolated cytoplasm (Wood & Andrews 1962). The vacuoles within the stained plasmodia are easily seen at low power in ISH with the *H. costale* probe (Fig. 5B). *Haplosporidium nelsoni* plasmodia were found in both connective tissue and epithelia (Figs. 4E, F; 5C; 6C); *H. costale* plasmodia were located throughout the connective tissue but not in the epithelium of the four oysters examined (Figs. 4C, D; 6B).

One oyster collected in October 1994 seemed to be infected with *H. costale* based on the presence of plasmodia and appropriately sized immature spores within sporocysts scattered throughout the connective tissue as determined by stained paraffin sections (Table 1). However, the diagnosis was recorded as tentative, because advanced infections of *H. costale* were known only from April to June (Andrews & Castagna 1978) and none had ever been reported from the fall season. *In situ* hybridizations using both *H. costale* and *H. nelsoni* DNA probes confirmed a mixed infection of the two parasites (Fig. 6), thus documenting unprecedented timing of an advanced *H. costale* infection. Plasmodia and sporocysts of *H. costale* were abundant in connective tissue (Fig. 6B), but not in epithelium; plasmodia of *H. nelsoni* occurred in epithelium (Fig. 6C) but not in connective tissue.

DISCUSSION

The PCR primers SSO-A and SSO-B and the DNA probe SSO1318 were sensitive and specific for the target organism, *H. costale*. Another set of PCR primers for *H. costale* was previously reported by Ko et al. (1995); however, we chose to target a different region of the SSU rDNA. The two regions targeted by the probe and primers described here are highly variable within the phylum Haplosporidia, accessible for probe hybridization and have

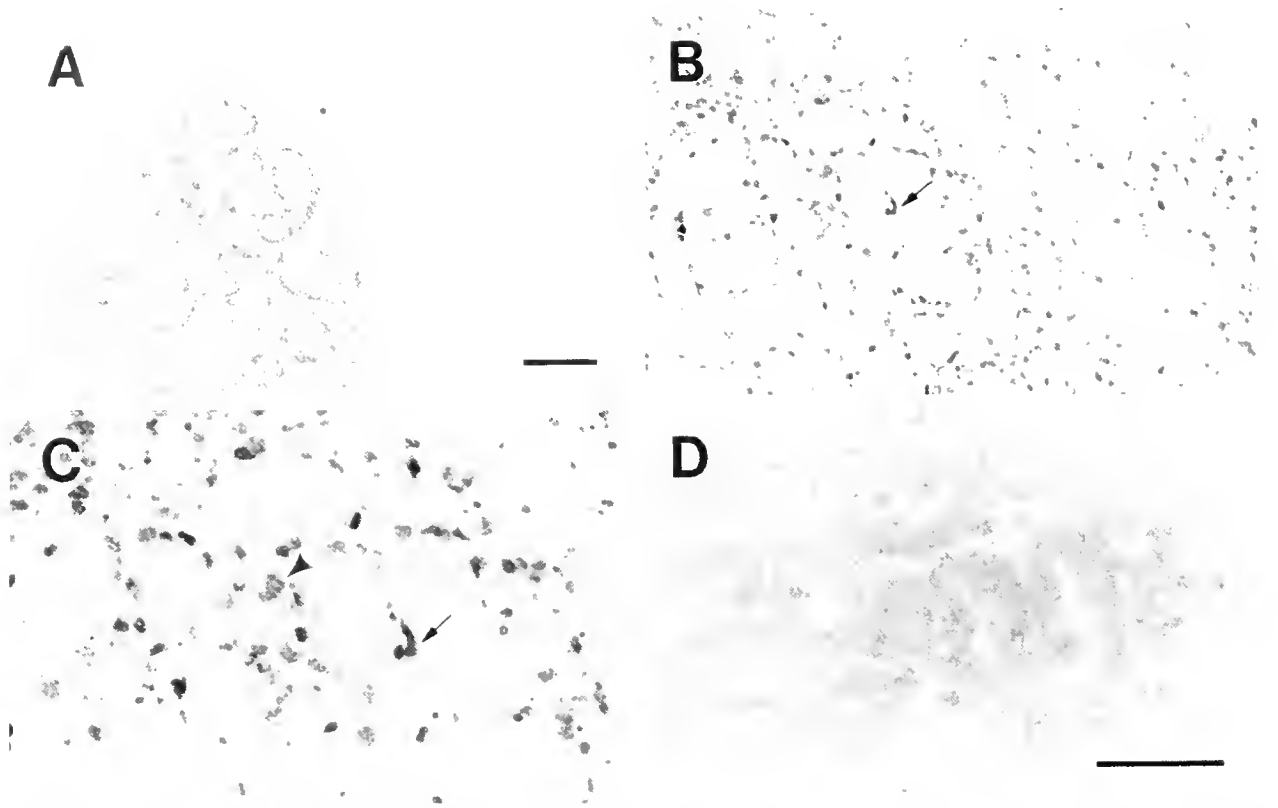

Figure 2. Consecutive histological sections of *H. costale*-infected *C. virginica* tissue (#181,676) showing plasmodia and sporocysts containing immature spores in the connective tissue. been used successfully for *H. nelsoni*-specific diagnostics (Stokes & Burreson 1995, Stokes et al. 1995a). The *H. costale* probe hybridized with *H. costale* plasmodia and immature spores, but not with mature spores, the same hybridization pattern as with the MSX probe with *H. nelsoni* (Stokes & Burreson 1995). In ISH of oyster samples from France, the SSO1318 probe did not hybridize with the Pacific oyster *C. gigas* nor with a haplosporidian infecting that host (Renault et al. 2000).

Mixed infections of *H. costale* and *H. nelsoni* that have not advanced to sporulation can now be diagnosed with confidence using these new tools. The plasmodia that hybridized with the *H. nelsoni* probe were not the same plasmodia that hybridized with the *H. costale* probe; although, these plasmodia were indistinguishable by traditional histological examination of stained tissue sections. The mixed parasite infections described here were originally diagnosed as being only *H. costale*. This diagnosis was undoubtedly made because of the preponderance of *H. costale* plasmodia and immature spores as compared to the relatively light infections of *H. nelsoni* and also because spores of *H. nelsoni* were absent. Couch (1967) reported finding mixed infections of *H. cos-*

tale and *H. nelsoni*, but they were based on the presence of spores of both species. In oysters tested to date with DNA probes, we have not observed *H. costale* plasmodia in the epithelium.

The inability to distinguish nonsporulating mixed haplosporidian infections by traditional histological examination may have skewed epizootiology data for high salinity regions in the past. It is possible that *H. nelsoni* has been more common in Virginia oysters in high salinity than previously reported. If so, this may raise questions about past disease data and oyster mortality attributed to *H. costale*.

Results of diagnoses using DNA probes have revealed an unprecedented seasonality of *H. costale* infections. The original diagnosis of *H. costale* infection in oyster #196,774 in October 1994 was uncertain. The plasmodia and immature spores throughout the connective tissue looked like *H. costale*, but the timing of this advanced infection was unusual. Epizootiological studies of *H. costale* had established the annual infection cycle as quite predictable. Clinical infections appear in the spring, as early as March, with sporulation and oyster mortality primarily in May and June. New infections occur before August 1st but remain subclinical

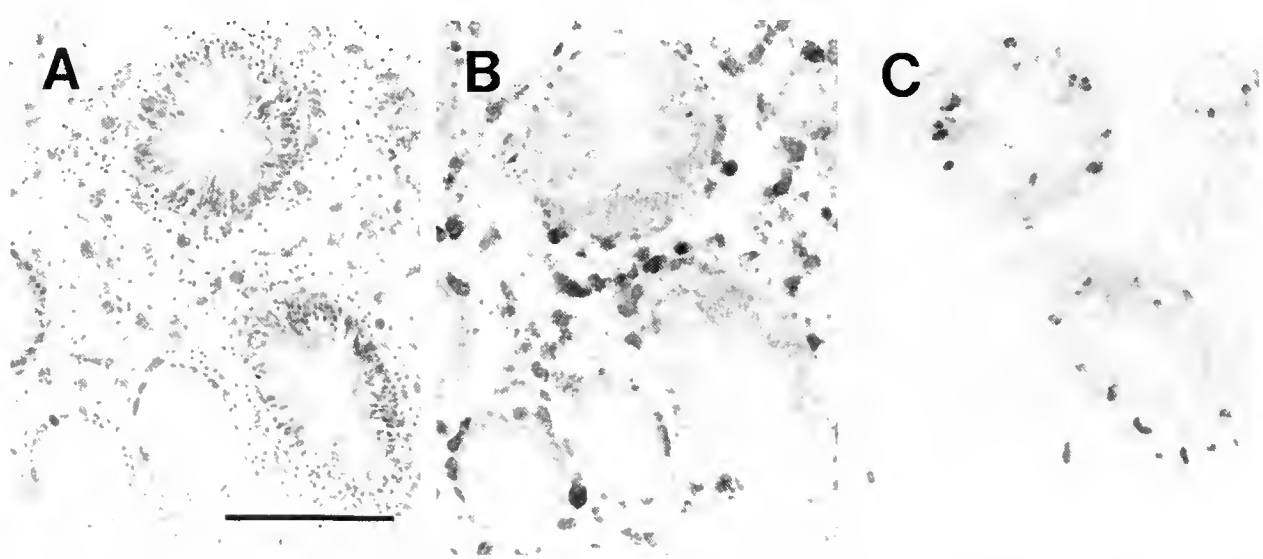

Figure 6. *In situ* **hybridization (ISH) of consecutive histological sections of oyster (#196,744) collected in October 1994 from Virginia's Eastern Shore with mixed haplosporidan infection. until the following spring (Couch & Rosenfield 1968, Andrews & Castagna 1978, Andrews 1988). Andrews and Castagna (1978) reported that numerous samples of seaside Virginia oysters from summer through winter revealed no *H. costale* infections. Diagnosis by DNA probes of oyster 196,774 confirmed the *H. costale* diagnosis, as about 80% of the plasmodia hybridized with the SSO1318 probe, but also revealed it as a mixed infection, because about 20% of the plasmodia hybridized with the MSX1347 probe. This *H. costale* infection, where the parasite's identity was confirmed by DNA-based diagnostics, did not meet historical criteria for SSO disease suggesting that the seasonality and epizootiology of this pathogen must be re-examined.

ANALYSES OF GONADAL CYCLING BY OYSTER BROODSTOCK, *CRASSOSTREA VIRGINICA* (GMELIN), IN LOUISIANA

JOHN E. SUPAN[1] AND CHARLES A. WILSON[2]

[1]*Office of Sea Grant Development, Louisiana State University, Baton Rouge, Louisiana 70803;* [2]*Coastal Fisheries Institute, Louisiana State University, Baton Rouge, Louisiana 70803*

ABSTRACT Oysters held near-shore in Caminada Bay, Louisiana during the summer, exhibit hypertrophic gonads with prominent genital canals beneath transparent mantle tissue about four weeks post-hatchery spawning, indicating recycling. Broodstock (N = 200) were analyzed histologically over a two-year period to document such gametogenesis, using Gonad/Body Ratios (GBR) and developmental stages. Ten oysters were randomly selected from a broodstock pool prior to each spawning attempt, and monthly during the winter-spring. As expected, the mean GBR before successful spawning attempts was significantly greater ($P \leq 0.05$) than the mean GBR before unsuccessful attempts. A dramatic drop in the percent occurrence of the advanced spawning and regression stage from May to June, a >40% spawning stage occurrence from May to October, and fluctuations in the percent occurrence of early and late developmental stages during the summer months illustrates gonadal recycling.

KEY WORDS: *Crassostrea virginica*, oyster, gonad, development, cycling, Louisiana

INTRODUCTION

Broodstock gonadal condition is fundamental to consistent production of oyster larvae (Lannan et al. 1980) and successful triploid induction (Downing & Allen 1987). Although temperature requirements for gonadal development and spawning have been reported for the southern variety of the eastern oyster (*C. virginica*) (Hopkins 1931, Hopkins et al. 1953, Loosanoff 1969, Hayes and Menzel 1981, Gauthier and Soniat 1989) documentation of the relationship between gametogenesis and induced spawning in the Gulf of Mexico region is limited. This is of particular interest, since oysters from southern populations are multiple spawners indicated by repeated gametogenic development throughout the spawning season (Ingle 1951, personal hatchery observations). An understanding of gonadal redevelopment is critical for collection of large numbers of viable eggs to produce commercial-scale broods, especially triploids (Allen et al. 1989)

Oysters held near-shore at the hatchery on Caminada Bay, Louisiana redevelop gonad and can be spawned repeatedly in the summer. Hypertrophic gonads with prominent genital canals beneath transparent mantle tissue can occur about 4 weeks post-spawning. Such gonadal activity stimulated interest in histological examination of gonadal cycling in the hatchery's broodstock. The purpose of this study was to document oyster broodstock gametogenesis, including winter development leading up to the spawning season, redevelopment (or recycling) between spawnings, and to determine the relationship between gonadal condition and spawning success.

MATERIALS AND METHODS

A broodstock of oysters was collected from oyster reefs in Louisiana and maintained in containers near-shore at the Sea Grant Grand Isle Bivalve Hatchery (29°15′12″N, 90°03′26″W) on Caminada Bay. Ten oysters were randomly selected over a two-year period for histological analyses when brought to the hatchery, prior to each spawning attempt, and bimonthly from the remaining broodstock during the winter-spring.

A 4–5 mm cross-section of each oyster was removed just posterior to the labial palp-gill junction and preserved in Davidson's fixative for histological processing (Howard & Smith 1983). A 4 µm section was obtained approximately 1,000 µm from the junction, mounted and stained with Gill's hematoxylin and eosin. This allowed the use of a standard cross section from each oyster for comparison. The sections were characterized by two H-shaped structures (large appendix of the stomach cecum) ventrally located in the histological sections as described by Morales-Alamo and Mann (1989).

Qualitative Description

Individual sections were microscopically examined to determine the sex and stage of gamete development for each oyster. Classifications included Early Development, Late Development, Spawning, and Advanced Spawning and Regression (ASR) after Kennedy and Krantz (1982).

Quantitative Analyses

Gonad/Body Ratios (GBR) were generated from histological sections similar to Kennedy and Battle (1964) using equidistant transects across each section to determine the gonadal width relative to body width (Fig. 1). Only transects 3 to 8 were used. However, preliminary statistical comparison of mean GBR's among transects indicated that transects from the dorsal and ventral regions of the gonads were different from the rest, likely a result of the shape of the right and left gonads (Fig. 1). Histological sections of oysters (N = 200) were analyzed to determine GBR differences among developmental stages and spawning attempts.

GBR was also measured in groups of oysters used during normal hatchery operation to determine how GBR varied between spawning and non-spawning populations. During each spawning attempt, approximately 150 oysters were removed from near-shore containers, 10 were randomly selected for histological analysis and the remainder were placed in a spawning table and exposed to ambient (30°–35°C) seawater for about 30 minutes. If necessary, the broodstock were then exposed to 18°C for approximately 1 hour, then re-exposed to ambient conditions for approximately 2 hours to stimulate spawning. If temperature stimulation did not

lead to spawning, the broodstock were exposed to a sperm suspension. Successful spawning was noted when a majority of the oysters had spawned, while unsuccessful spawning was characterized by little or no spawning activity.

The GBR's were analyzed using analysis of variance (ANOVA) with a two-way fixed factorial model (SAS Institute 1991) to test the difference among spawning attempts. The model included GBR as the dependent variable, spawning result as a fixed effect, and developmental stage and its interaction with the spawning result as random effects. The GBR's met the assumptions of normality and variance homogeneity after angular transformation (Dowdy and Wearden 1991). Tukey's Honestly Significant Difference Procedure was used to test the difference (α = 0.05) among developmental stage and spawning result.

RESULTS

Quantitative Analyses

As expected, all developmental stages had significantly different mean GBR's ($P \leq 0.05$)(Table 1) and the mean GBR during successful spawning attempts was significantly greater (mean = 0.51, $P \leq 0.05$) than the mean GBR during unsuccessful attempts (mean = 0.45)(Table 2).

Successful	0.51	0.10	A
Unsuccessful	0.45	0.12	B

* Ratio = Arcsin (√ (Gonad Width/Body Width)).
** Tukey's Honestly Significant Difference (α = 0.05).
SD = Standard Deviation.

Qualitative Analyses

After evaluating the histological sections for developmental stage (Kennedy and Krantz 1982), it became apparent that oyster gonads were recycling. Histological sections representing Early Development (Fig. 2, A & B), Late Development (Fig. 3, A & B), Spawning (Fig. 4, A & B) and Advanced Spawning-Regression (ASR)(Fig. 5, A & B) where noticeably different than sections from recycling (Fig. 6, A & B). ASR gonads were typically atretic, with significant amounts of cellular debris and amoebocytes in

LG = left gonad, DD = digestive diverticula, M = mantle, GI = gill, G = gonad, F = follicles, CT = connective tissue, CG = genital canal.

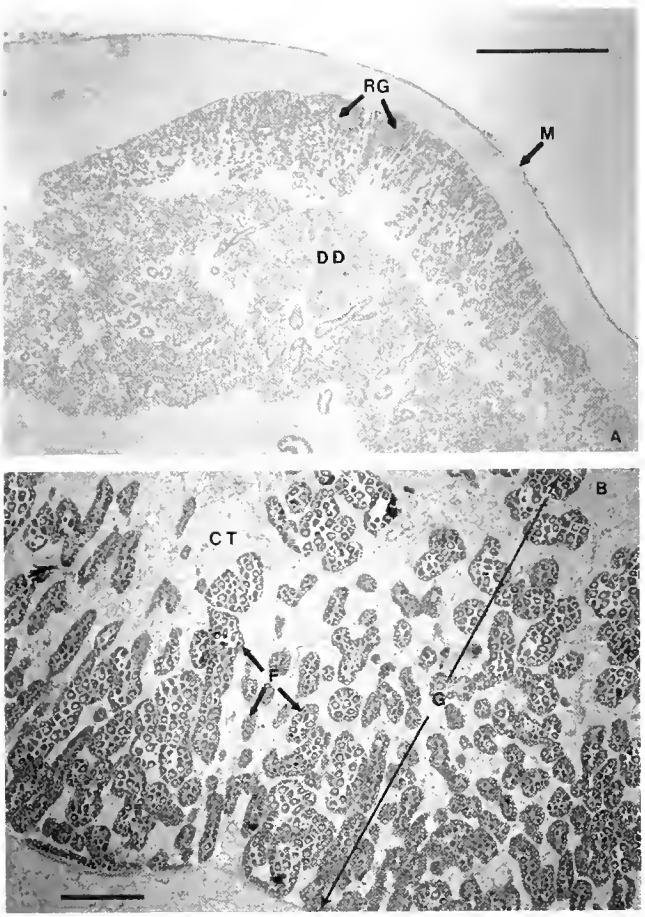

Figure 3. A & B. Photomicrographs of histological sections showing later gonadal development (April) of *C. virginica*,posterior-dorsal region (A: bar = 200μ; B: bar = 30μ). RG = right gonad, DD = digestive diverticula, M = mantle, G = gonad, F = follicles, CT = connective tissue.

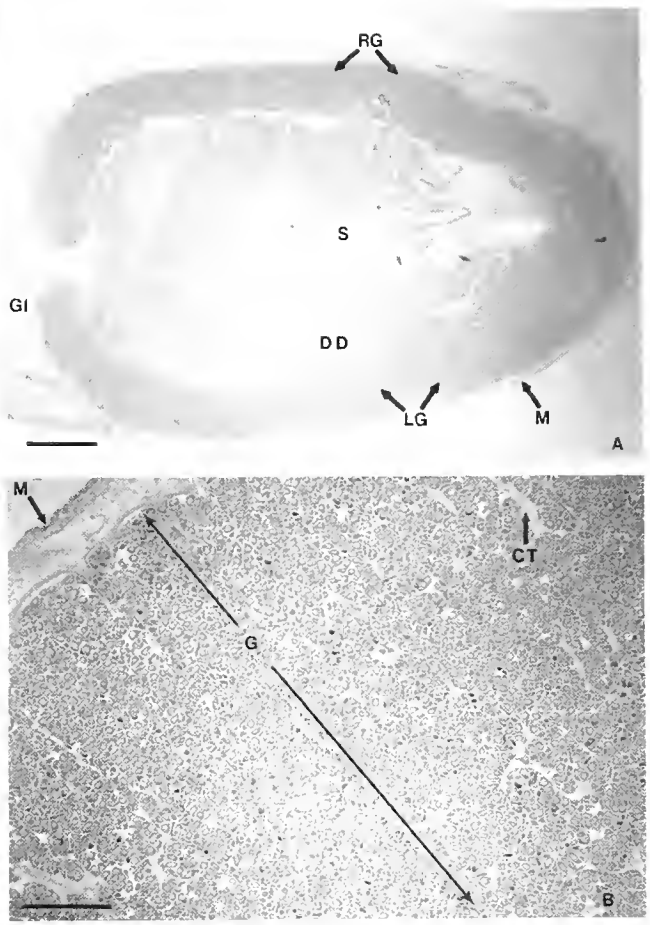

Figure 4. A & B. Photomicrographs of histological sections showing spawning gonadal development (June) of *C. virginica*. (A: bar = 200μ; B: bar = 30μ, posterior-dorsal region). RG = right gonad, LG = left gonad, DD = digestive diverticula, M = mantle, GI = gill, S = stomach, G = gonad, CT = connective tissue.

nearly empty follicles and surrounding connective tissue. In contrast, recycling gonads were characterized by proliferation of developing follicles typically found in Early and Late Development sections (i.e., enlarged germinal cells and young pendant primary oocytes in females [Kennedy & Battle 1964]).

Figure 7 illustrates the gametogenic cycle produced by the descriptive stage characterization conducted during this study. A high percentage of the oysters examined were in Early Development at the beginning of the year; this stage decreased from May to November, rose during September, and increased again in December. A short occurrence of Late Development in the spring during the sharp rise in the occurrence of the Spawning stage shows how oysters held in the near-shore waters of Grand Isle rapidly developed toward spawning condition. The percent of oysters in Later Development fluctuated during the summer. The occurrence of ASR reached 60% during April to May, decreased to approximately 25% during May to June, remained stable during the summer, and increased dramatically beginning in September to October.

DISCUSSION

Quantitative Results

The difference between the mean GBR of oysters that spawned and those that did not was as expected (Table 2). Oysters in spawning condition should have higher GBR's than non-spawning oysters. Follicles anastomose through the surrounding connective tissue during gonadal development (Figs. 2–6) increasing the mean GBR. The creamy-white appearance of a sexually mature oyster is due to the hypertrophy of the gonad (Kennedy & Battle 1964; Fig. 1).

Fecund oysters are prolific spawners. Such spawning activity is reflected in the mean GBR's in Table 1, which depict gonadal attrition between spawning (0.52) and advanced spawning and regression (0.38). Hormonal control (Morse et al. 1978), genetics (Lannan 1980) and food availability to broodstock are examples of the many sources of variation in obtaining successful oyster spawning.

Qualitative Results

The occurrence of oysters in Spawning stage in Figure 7 depicts an expected curve of over 60% occurrence during May to October, with reductions in the winter and spring. A similar autumn gonadal state has also been documented in Louisiana (Gauthier & Soniat 1989).

One would think that a line depicting an ASR gonadal stage would sharply increase from June to December, but this is not evident in Figure 7. The line depicts the highest ASR occurrence

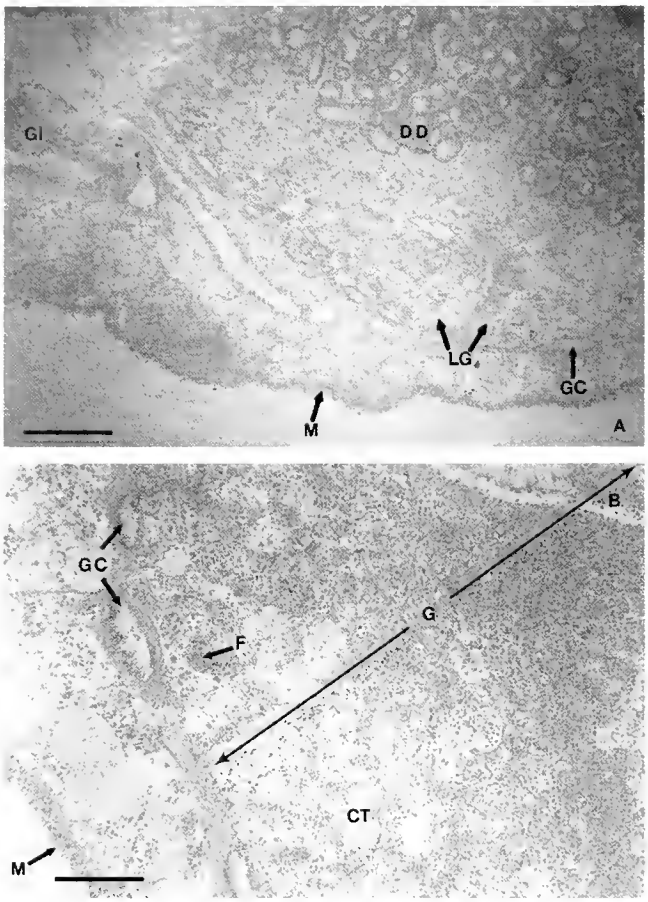

Figure 5. A & B. Photomicrographs of histological sections showing advanced spawning and regression gonadal development (August) of *C. virginica*, posterior-ventral region (A: bar = 200μ; B: bar = 30μ). LG = left gonad, DD = digestive diverticula, GC = genital canal, M = mantle, GI = gill, G = gonad, CT = connective tissue, F = follicle.

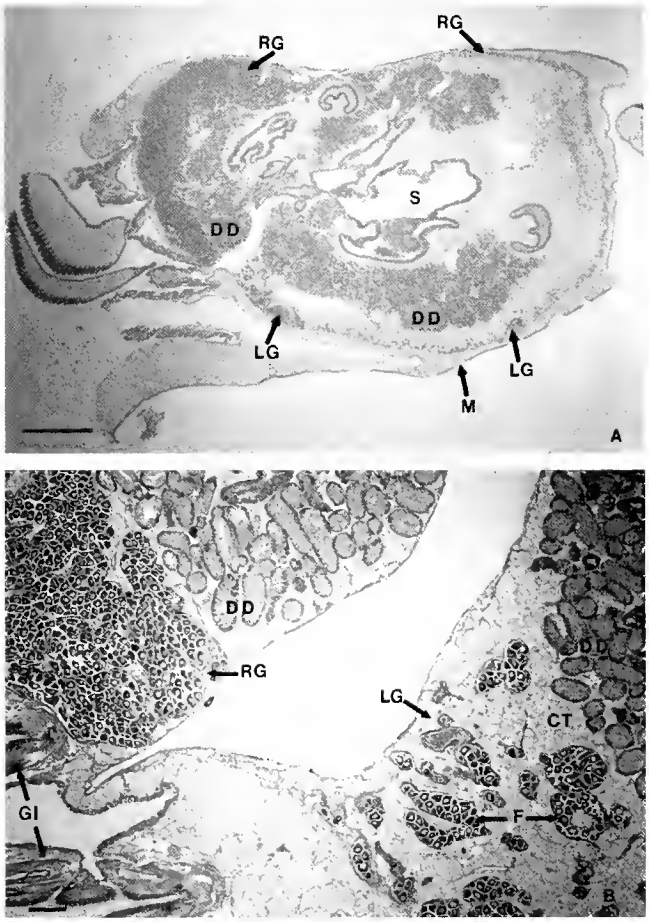

Figure 6. A & B. Photomicrographs of histological sections showing gonadal recycling (October) of *C. virginica* (A: bar = 200μ; B: bar = 30μ; ventral region). RG = right gonad, LG = left gonad, DD = digestive diverticula, S = stomach, M = mantle, GI = gill, CT = connective tissue, F = follicle.

in May (60%) and December (80%) with lower occurrences (24%–39%) during June to July.

The dramatic drop in ASR occurrence and the rather steady occurrence of the Spawning stage, as well as fluctuations in the percent occurrence of Early and Later Developmental stages during the summer months, illustrates recycling during June to October. This may or may not be evidence of spawning in the wild since the samples were taken from suspended broodstock coerced to spawn at the hatchery during the study.

Nevertheless, comparison of Figures 2 to 5 with Figures 6, 8 and 10 shows how gonadal recycling is occurring in the broodstock held at the Grand Isle hatchery. The follicles of the left gonad depicted in Figure 6 (B) and those depicted in Figure 8 (B) are similar to those found during Early and Later Development (Figs. 3 and 4). Atresia is evident in the dorsal region of the right and left gonads in Figure 6 (A) and in the nearby connective tissue and follicles in Figures 6 (B) and 8 (B). This atresia is similar to that found in Advanced Spawning and Regression (Fig. 5). The right gonad in Figure 6, Figure 8 (A), and Figure 9 are similar to the gonads in Spawning stage oysters in Figure 6, with no noticeable atresia nor reduction in oocyte organization within the follicles (Kennedy & Krantz 1982).

The description of ASR by Kennedy and Krantz (1982) included the occurrence of early gametogenic stages remaining on the follicle walls and the reappearance of connective tissue in the interfollicular areas with invading phagocytic cells. The use of an additional developmental stage, recycling, including the presence of early and later development characteristics plus the presence of atresia, is recommended to improve the characterization of gonadal development in Louisiana.

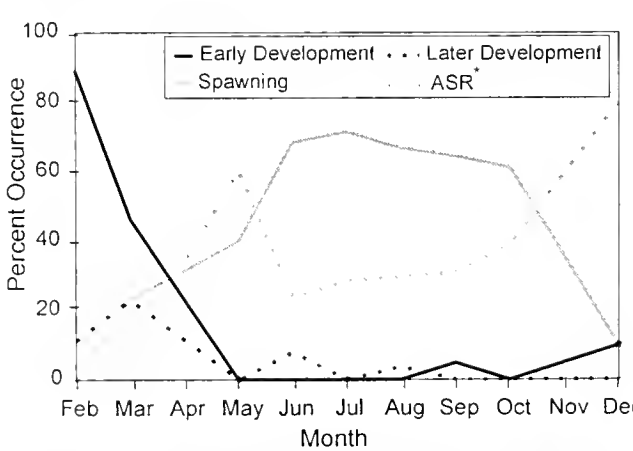

Figure 7. Percent occurrence of gonad development stage of *C. virginica* by month. * denotes advanced spawning and regression.

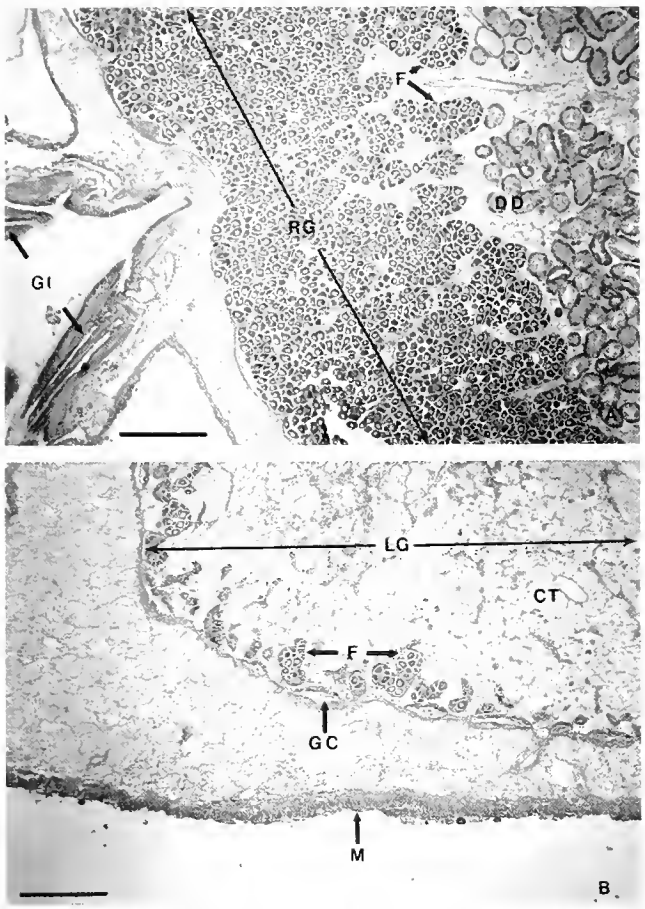

Figure 8. A & B. Photomicrographs of histological sections showing gonadal recycling (August) of *C. virginica* (A: bar = 200μ; B: = 200μ, dorsal region). RG = right gonad, LG = left gonad, DD = digestive diverticula, M = mantle, GI = gill, CT = connective tissue, S = stomach, GC = genital canal.

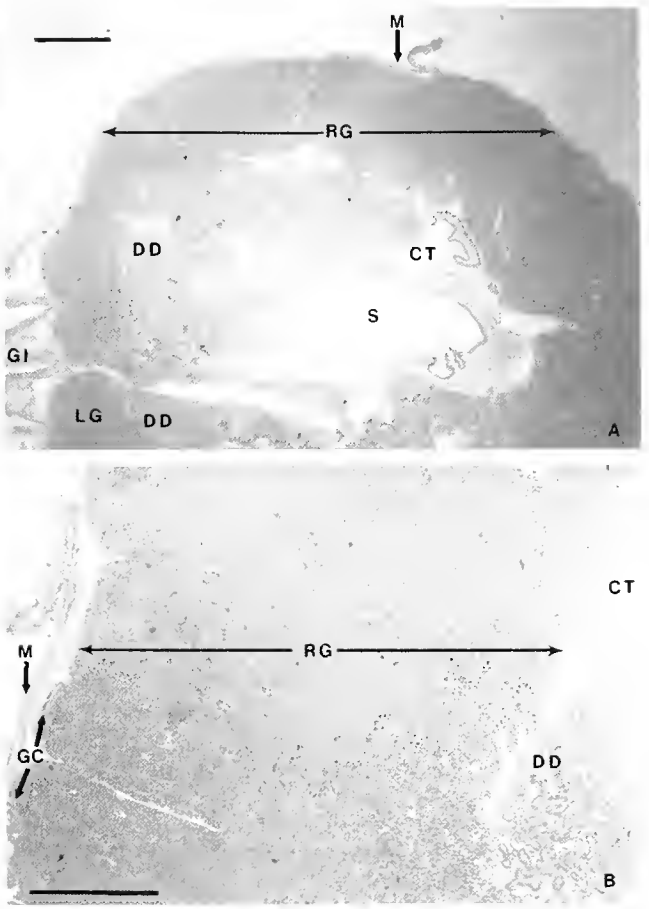

Figure 9. A & B. Photomicrographs of histological sections showing gonadal recycling (August) of *C. virginica* (A: bar = 200μ; B: bar = 200μ, dorsal region). RG = right gonad, LF = left gonad, DD = digestive diverticula, M = mantle, GI = gill, CT = connective tissue, S = stomach, GC = genital canal.

Histological sectioning is expensive and, therefore, not a valuable tool for evaluating hatchery broodstock. Gonadal recycling of broodstock held near-shore is visually apparent, however, by the observance of transparent mantle tissue occurring with a spotty or hypotrophic gonad during early recycling, followed by a full or hypertrophic gonad after complete recycling.

ACKNOWLEDGMENTS

We are grateful to Jordan Bradford, Lee Hanson, the late Tony Venterella and his wife, Gayle, and the late Carlo Venterella for their logistical support during the project, and Mr. Ron Becker for financial support. We thank Cheryl Crowder for the histological preparations and Stephanie Ehrett for assistance with section analyses. We are also grateful to Dr. Stan Allen for his review of the manuscript. Thanks is extended to the following for providing broodstock: Peter Vunjnovich, Wilbert Collins, Jules Melancon, Jordan Bradford, and James Cheramie. Financial support was provided by grants from the Louisiana Board of Regents [LEQSF (93-96)-RD-B-08] and the Louisiana Sea Grant College Program [NA89AA-D-SG226].

A COMPARATIVE FIELD STUDY OF *CRASSOSTREA ARIAKENSIS* (FUJITA 1913) AND *CRASSOSTREA VIRGINICA* (GMELIN 1791) IN RELATION TO SALINITY IN VIRGINIA

GUSTAVO W. CALVO,* MARK W. LUCKENBACH, STANDISH K. ALLEN, JR., AND EUGENE M. BURRESON

School of Marine Science, Virginia Institute of Marine Science, College of William & Mary, Gloucester Point, Virginia 23062

ABSTRACT We examined survival, growth, and disease susceptibility of triploid *Crassostrea ariakensis* (= *rivularis*) and compared results with that of diploid *Crassostrea virginica*. Two hundred and fifty oysters (age = 2 yr, mean shell height = 60–64 mm) of each species were deployed at duplicate sites, (Chesapeake Bay, and the Atlantic Coast of Virginia) within low, medium, and high salinity regimes respectively (< 15‰, 15–25‰, > 25‰). Over the course of the study, from June 1998 to September 1999, *C. virginica* exhibited low survival, modest growth and high disease susceptibility. In contrast, *C. ariakensis* exhibited high survival, high growth rate, and low disease susceptibility. At low salinity sites, final mean cumulative mortality of *C. virginica* (81%) was significantly higher than that of *C. ariakensis* (14%). At medium and high salinity sites, all *C. virginica* died before the end of the study whereas final mean cumulative mortality in *C. ariakensis* was 13 to 16%. After 1 year of deployment, mean shell height of *C. virginica* at low, moderate, and high salinity sites was respectively 70, 80 and 73 mm. In comparison, mean shell height of *C. ariakensis* was respectively 93, 121 and 137 mm. At low salinity sites, mean growth rate of *C. virginica* was not significantly different from that of *C. ariakensis*. At medium and high salinity sites, mean growth rate of *C. virginica* was significantly lower than that of *C. ariakensis*. Prevalence and intensity of *Perkinsus marinus* infections were significantly higher in *C. virginica* than in *C. ariakensis*. During the second summer of disease exposure, prevalence in *C. virginica* was 100% at all sites whereas in *C. ariakensis* it ranged from 0 to 28%. Heavy intensity of infections were prevalent in *C. virginica* whereas infections in *C. ariakensis* were limited to light intensity. *Haplosporidium nelsoni* (MSX) was present in *C. virginica*, but absent in *C. ariakensis*. Mud worms (*Polydora* spp.) were present in both oyster species, but infestations were low and did not appear to affect condition or growth. In summary, wide salinity tolerance and low disease susceptibility were associated with high survival and growth of *C. ariakensis* in Chesapeake Bay and the Atlantic Coast of Virginia.

KEY WORDS: Chesapeake Bay, aquaculture, species introduction, *Crassostrea ariakensis*, *C. virginica*

INTRODUCTION

In contrast to extensive information available on the eastern oyster *Crassostrea virginica*, and Pacific oyster *Crassostrea gigas*, reports on the Suminoe oyster *Crassostrea ariakensis* (= *C. rivularis*), are scarce. Suminoe oysters have been reported to be naturally distributed from southern Japan along the south China coast through southeast Asia to the western coast of the Indian subcontinent, but the taxonomy is tenuous in some areas and its actual distribution not clearly known (Carriker & Gaffney 1996).

Larval settlement for *C. ariakensis* is reported to occur primarily in estuarine areas with low salinity, but juvenile and adult oysters grow within a wide range of salinity (Guo et al. 1999, Ahmed et al. 1987, Cai et al. 1992). Cultivation is important in southern China using seed oysters collected from the wild (Guo et al. 1999). On the West Coast of USA, where *C. ariakensis* was introduced with shipments of *C. gigas* and kumamoto oysters (*Crassostrea sikamea*, Anemiya 1928) from southern Japan in the 1970s (Breese and Malouf 1977), its aquaculture potential has been established (Langdon and Robinson 1996). Using field experiments to compare the growth of *C. ariakensis* and *C. gigas*, Langdon and Robinson (1996) found that both species had similar growth and meat condition at various locations along the West Coast.

To the best of our knowledge, no parasitic diseases have been reported in Suminoe oysters within its native range. However, in Zhanjiang Bay, southern China, mass mortality of *C. ariakensis* has been associated with outbreaks of toxic phytoplankton blooms (Yongjia et al. 1995). In Marennes Oleron, France, mortality in association with *Bonamia*-like parasites was observed in quarantined *C. ariakensis* animals exposed to *Bonamia ostreae* endemic waters (Cochennec et al. 1998).

Studies on the potential performance and disease susceptibility of Suminoe oysters are not available for the Atlantic Coast of USA. However, as native eastern oyster stocks collapsed throughout much of the mid-Atlantic seaboard due to over harvesting, disease, and water quality deterioration, interest in the potential use of non-native oyster species has grown. Following a Virginia program to examine the suitability of non-indigenous oyster species to the local environments (VIMS 1996), *C. gigas* was the first species to be evaluated in Chesapeake Bay and the Atlantic Coast of Virginia (Calvo et al. 1999). Over the course of that study, from May 1997 to 1998, *C. gigas* had lower disease susceptibility than *C. virginica*, but survival and growth were equal or superior in native oysters than in *C. gigas* within Chesapeake Bay. Based on its close resemblance to the native oyster and its tolerance of temperate to sub-tropical environments, *C. ariakensis* was the second candidate species selected for testing in Virginia (VIMS 1996). Considering its documented ability to grow in a wide range of salinity, we hypothesized that *C. ariakensis* would perform better relative to *C. virginica* than had *C. gigas* in Chesapeake Bay. The objectives of the present study were to compare survival, growth, disease susceptibility and infestations by shell boring polychaetes in *C. ariakensis* and *C. virginica* deployed over a range of salinity.

MATERIALS AND METHODS

Study Sites

Six sites were selected based several criteria including salinity regime, geographic location, available information on oyster growing conditions and water quality, safety, logistics, and relevance

*Corresponding author. E-mail: calvo@vims.edu

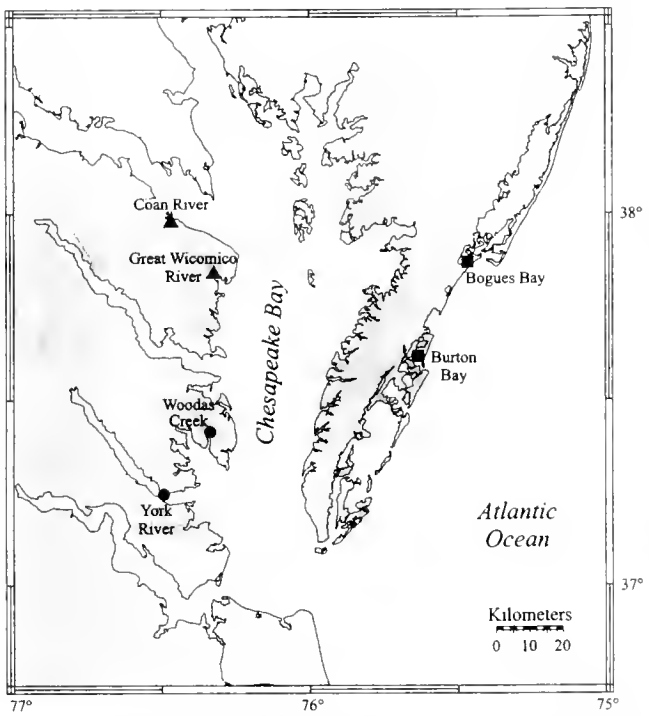

Figure 1. Location of study sites in Chesapeake Bay and the Atlantic Coast of Virginia: ▲ = Low salinity (<15‰) sites, ● = Medium salinity (15–25‰) sites, ■ = High salinity (>25‰) sites.

for the oyster industry. Sites were established at duplicate locations within low salinity (<15‰), medium salinity (15–25‰), and high salinity (>25‰) areas (Fig 1). Low and medium salinity sites were established near the margins of rivers (Coan, Great Wicomico, and York) or in shallow creeks surrounded by marshes (Woodas Creek, a tributary of the East River). High salinity sites were located in well-flushed narrow channels surrounded by marshes and mudflats in the coastal lagoon system of the Atlantic Coast of Virginia.

Temperature and salinity were measured during monthly site visits with a stem thermometer and a refractometer. To further characterize environmental variables, hourly temperature, salinity, and turbidity were measured with Hydrolab-Minisonde® dataloggers deployed at the same sites for weekly to monthly intervals.

Oysters

Individually certified triploid *C. ariakensis* were produced and maintained in quarantine first at the Haskin Shellfish Research Laboratory, Rutgers University (HSRL) and then at the Virginia Institute of Marine Science's (VIMS) Aquaculture Genetics and Breeding Technology Center. *Crassostrea ariakensis* brood stock, originating from an established line maintained in quarantine at HSRL and derived from sources on the West Coast of USA, was spawned in July 1996. Triploidy was induced by treatment of fertilized eggs with cytochalasin-B using the methods described by Downing and Allen (1987) and Allen et al. (1989). Juvenile *C. ariakensis* were transferred to flow-through York River water with quarantined effluents at VIMS, where oysters were maintained until they were individually examined for triploidy, as described later, before field deployment in early 1998. *Crassostrea virginica* brood stock, collected from Mobjack Bay, VA was spawned by a local commercial hatchery (Middle Peninsula Aquaculture) in July 1996. Prior to deployment, diploid *C. virginica* juveniles were maintained by Mobjack Bay Seafood in the Ware River, VA.

Experimental Design

Between May 29 and June 2, 1998, adult oysters were dispensed into replicate 9.5-mm mesh bags and placed within individual floating trays at the study sites. There were two replicate sites within each of three salinity regimes (Fig. 1). Each floating tray contained two bags with 100 oysters and one bag containing 50 individually labeled oysters, to follow growth, as described later. Floating trays (2.3 m × 0.5 m × 0.3 m) were constructed by fitting wire mesh trays (25-mm square 16 gauge mesh) into floating frames built with 4-inch (10.16 cm) PVC pipe, following the design of Luckenbach and Taylor (1997). Floating trays and bags were cleaned of fouling organisms at least once a month during regular site visits and more often if necessary. All sites were visited monthly (± 15 days).

Mortality, Growth and Condition

All live and dead oysters within each float were counted monthly to determine survival. Monthly mortality was calculated as the number of oysters that died during each month interval, divided by the number of live oysters at the beginning of the month, corrected for oysters removed by sampling. Cumulative mortality was calculated as the sum of interval mortality (Barber and Mann 1994, Krebs 1972). Mortality data was examined for normality and homogeneity of variance using plots of means versus standard deviations and Bartlett's chi-square test (Zar 1974). A two-way ANOVA was employed to examine the effects of species and salinity on arcsin-transformed cumulative mortality. Statistical analyses were performed using Statview® and Statistica® software.

To follow growth, 50 oysters within each float were individually labeled and shell height was repeatedly measured to the nearest 0.1 mm using calipers, once monthly except January, February, and April 1999. Monthly growth rates for individual oysters were calculated as the overall shell height increment during the growing period while live oysters of both species were still available at all sites, June 1998 to May 1999, and divided by the deployment time in days standardized to 30 days. When oysters died measurements were taken from the remaining individuals without replacement. Growth rate data was examined for normality and homogeneity of variance using the same tests specified above for mortality data. The effects of species and salinity regime on arcsin-transformed mean growth rate were examined using a two-way ANOVA followed by a Newman-Keuls test.

At the end of the experiment, in September 1999, whole weight, shell weight, tissue wet and dry weights were measured on the same oysters collected for disease diagnoses. Following Lawrence and Scott (1982), Condition Index (CI) was calculated by the formula:

$$CI = \text{tissue dry weight} * 100 / (\text{whole weight} - \text{shell weight}). \quad (1)$$

Oysters were allowed to air-dry for 15 to 20 minutes before weighing and whole oyster weight was recorded to the nearest 0.01g. Oysters were then shucked, shells weighed to the nearest 0.01g, and wet tissues were gently rolled on a paper towel and weighed on pre-tarred vessels to the nearest 0.001g. Wet tissues were dried at 80°C overnight and tissue dry weight was measured the next day

to the nearest 0.001g. Condition index data was examined for normality and homogeneity of variance using the same tests specified above for mortality data. Non-parametric statistics were employed because means and standard deviations were still highly correlated ($r = 0.952$) after transformation. Mann-Whitney tests were used to examine differences in mean condition index and mean ranked body weights between species. Kruskal-Wallis tests were employed to examine differences in the above parameters among salinity regimes.

Diseases and Polydora

A baseline sample of 25 oysters was taken to assess the disease status of each species prior to deployment in May 1998. Subsequent samples of each species at each site were collected in August and September 1998, and in May, August, and September 1999. *Perkinsus marinus* was diagnosed using Ray's fluid Thioglycollate medium (RFTM) assays (Ray 1952) on combined mantle, gill, and rectal tissue. Infection intensity was rated based on Ray (1954) and Mackin (1962). For the calculation of weighted prevalence infection intensity was ranked, following Paynter and Burreson (1991), as: 0 = negative, 1 = light, 3 = moderate and 5 = heavy. Light-moderate infections were ranked as 1 and moderate-heavy infections were ranked as 3. Weighted prevalence was calculated by the formula:

$$\text{Weighted prevalence} = \Sigma I^{*} n_I / N \qquad (2)$$

Where I = infection intensity rank
n_I = number of oysters within I
N = total number of oysters examined in the sample.

Prevalence and weighted prevalence data were examined for normality and homogeneity of variance using the same tests specified above for mortality data. Two-way ANOVAs followed by Newman-Keuls tests were employed to analyze the effects of species and salinity regime on arcsin-transformed prevalence and untransformed weighted prevalence.

Haplosporidium nelsoni, the causative agent of MSX disease, was diagnosed using standard paraffin histology procedures with oysters preserved in Davidson's AFA and 6 μm tissue sections stained with Harris' hematoxylin and eosin (Burreson et al. 1988). Infection intensity was rated as light, moderate or heavy based on Burreson et al. (1988). Histology sections were also used to document the presence of other parasites and to examine development of oyster gonads. Disease diagnoses and histology were performed by the VIMS Shellfish Pathology Laboratory.

The spionid polychaetes *Polydora websteri* and *P. ligni* are commensal with bivalves, including oysters. These suspension-feeding worms do not feed on the oyster, but the mechanical irritation caused by their presence causes the oyster to lay down additional layers of conchiolin over the worm's tube in what are often termed mud-blisters. At sufficiently high levels of infestation this can severely limit the growth of oysters and reduce their condition index. Examination for mud-blisters associated with *Polydora* spp. was conducted on the same oysters collected for condition and disease diagnoses in September 1999. Worms were not identified to species, but *Polydora websteri* is the most common species affecting oysters in the northeast coast of the United States (Blake and Evans 1972, Wargo and Ford 1993). The internal surface of right valve shells was visually inspected and rated according to the presence and extent of mud-blisters. Examination was restricted to right valves as in Wargo and Ford (1993) who reported that infestations by *Polydora* spp. were equally found in right and left valves. Following the methods of Handley and Bergquist (1997), infestation was rated as: (0) no visible mud-blisters or any evidence of boring by *Polydora* spp.; (1) mud-blisters affecting less than 25% of the valve; (2) 25–50% of the valve affected; (3) 50–75% of the valve affected; or (4) more than 75% of the valve affected. Weighted prevalence was calculated similarly to equation (2) using the five categories above. Prevalence and weighted prevalence data was examined for normality and homogeneity of variance using the same tests specified above for mortality data. Non-parametric tests were employed because zero variances precluded computation of Bartlett's test for determining homogeneity of variance. Mann-Whitney tests were used to examine differences in mean prevalence and mean weighted prevalence between species. Kruskal-Wallis tests were employed to examine differences in the above parameters among salinity regimes.

Reproductive Status and Ploidy

A baseline sample of *C. ariakensis* was collected to ascertain the percentage of triploid individuals in the lot of animals exposed to Cytochalasin-B as described above. Prior to field deployment, all *C. ariakensis* animals were individually certified as triploids following flow-cytometric methods (Allen 1983). Briefly, experimental animals were notched on the dorsal side of the right valve using a Dremel® rotary tool equipped with a fiberglass-cutting wheel. A 1- ml syringe fitted with a 23-gauge needle was inserted into the adductor muscle and 0.05 ml of hemolymph was removed. A 10 μg/ml DAPI-10% DMSO staining solution was added to the hemolymph and the sample was vortexed, aspirated, and filtered through a 23μm Nitex® screen. DNA content of prepared samples was determined on a PARTEC® Cell Cycle Analyzer via ultraviolet light excitation. Histograms of relative DNA content were used to identify diploid cells with modal DNA values 1.5 times lower than that of triploid cells. Individuals with triploid and diploid cells were categorized as mosaics. A 2mm × 2mm piece of gill tissue, as well as a cross-section of gonad tissue were also sampled from mosaic individuals and examined for DNA content as above. The remaining gonad from mosaic individuals was processed by histology.

Over the course of the experiment, samples of *C. ariakensis* (n = 16–35) were collected from each site in July and August 1998 and in May, June, and July 1999. Ploidy assays were conducted at HSRL and the VIMS Aquaculture Genetics and Breeding Technology Center. A two-way ANOVA was employed to examine the effects of salinity and time on mean arcsin-transformed percentage of mosaics. Significant effects were further examined using a Newman-Keuls test.

RESULTS

Environmental Parameters

Means of monthly salinity measures at the two low salinity sites were below 10‰ only during June and July 1998. Drought conditions prevailed throughout much of the study and salinities above 15‰ were recorded at the low salinity sites from November 1998 to March 1999. Medium salinity sites experienced relatively low salinity (<15‰) during June 1998, but were between 15 to 25‰ on all other sampling dates (Fig. 2). Salinity fluctuations in

high salinity sites were within the expected range (25–35‰). Temperature followed similar seasonal trends at all sites with a maximum of 28° to 32°C in July and a minimum of 0° to 5°C in March. High salinity sites experienced overall cooler temperature with monthly means 2° to 4°C lower than medium or low salinity sites (Fig. 2). Turbidity was low (<70 Nephelometric turbidity units at all sites and times tested). Dissolved oxygen was relatively low (60% air-saturation) at Woodas Creek in July 1999 compared to all other sites and times measured (68–87% air-saturation).

Mortality

As the experiment progressed, *C. virginica* percent cumulative mortality rapidly increased whereas *C. ariakensis* mortality remained low. The highest increase in mean cumulative mortality, from 5% to 78%, was observed in *C. virginica* at medium salinity between July and October 1998 (Fig. 3). At the end of the experiment, mean cumulative mortality in *C. virginica* (81%–100%) was significantly higher ($p < 0.0005$) than that in *C. ariakensis* (13%–16%). Salinity had a significant ($p = 0.006$) effect on final cumulative mortality. The interactive effect of species and salinity was also significant ($p = 0.011$) and may be attributed to the increase in mortality between low and higher salinities observed for *C. virginica* whereas low mortality was similarly observed for *C. ariakensis* at all salinities (Fig. 4).

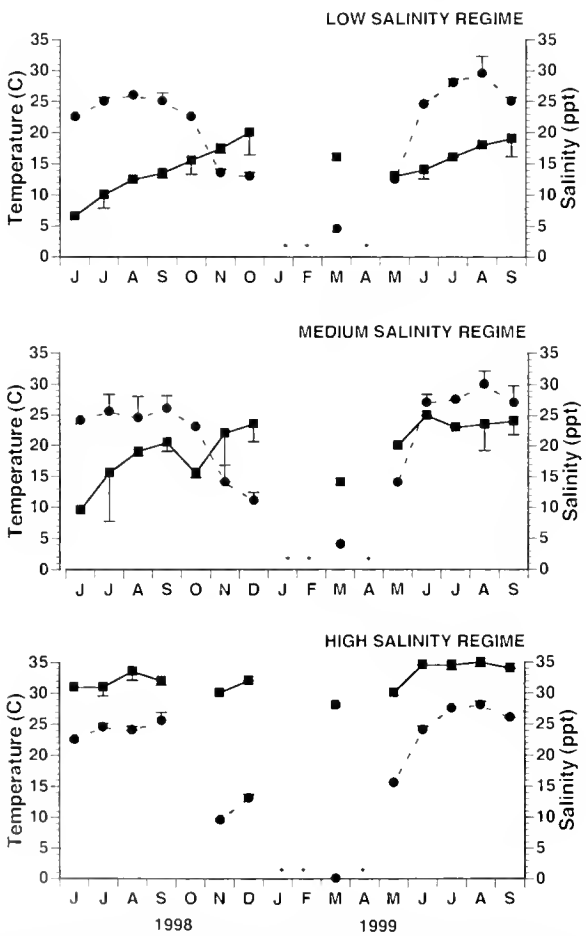

Figure 2. Means of monthly temperature and salinity measurements by salinity regime (N = 2 sites, ± SD), from June 1998 to September 1999. ● = Temperature using stem thermometer. ■ = Salinity using refractometer.

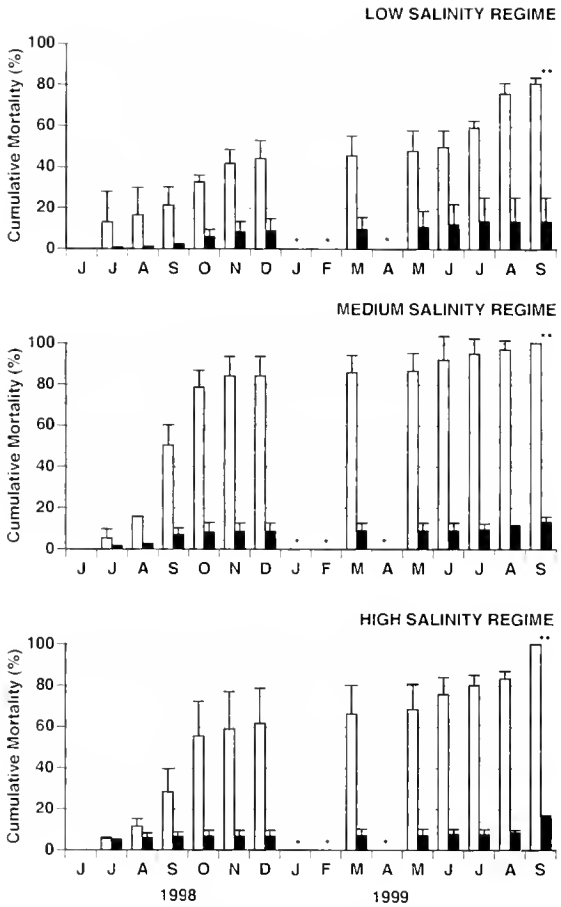

Figure 3. Mean cumulative mortality by salinity regime (N = 2 sites, + SD) from May 1998 to September 1999. Open bars = *C. virginica*. Solid bars = *C. ariakensis*. ** = Significant at $\alpha = 0.01$. NS = Not sampled.

Growth

Growth varied with species and salinity regime (Fig. 5 and Table 1). At the start of the experiment mean shell height was 60 mm in *C. virginica* and 64 mm in *C. ariakensis*. After 1 year of deployment, in May 1999, mean shell height of *C. virginica* at low, medium, and high salinity sites was respectively 70, 80 and 73 mm. In comparison, mean shell height of *C. ariakensis* at low,

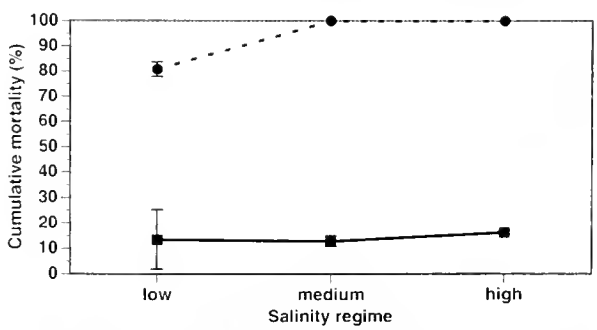

Figure 4. Interaction between oyster species and salinity on final cumulative mortality. Means of 2 sites (± SD). ● = *C. virginica*. ■ = *C. ariakensis*.

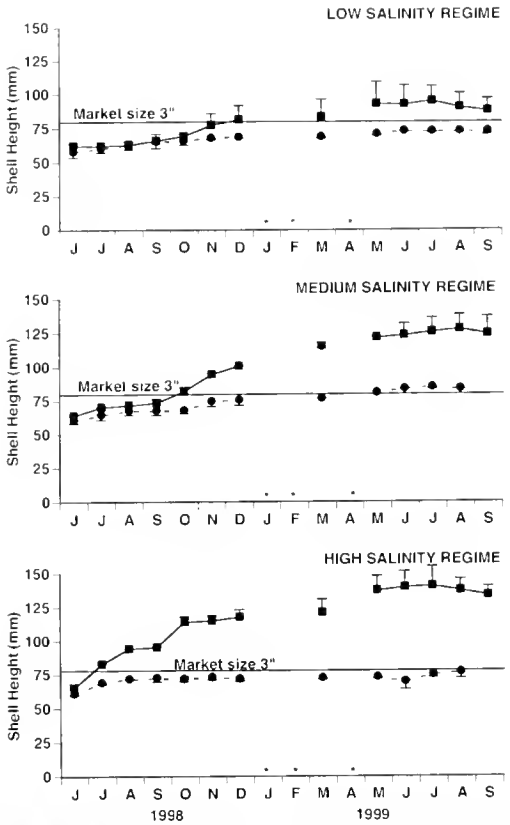

Figure 5. Mean shell height by salinity regime (N = 2 sites, ± SD) of 50 individual oysters repeatedly measured from May 1998 to September 1999. ● = *C. virginica*. ■ = *C. ariakensis*.

moderate, and high salinity sites, was respectively 93, 121 and 137 mm. Oysters continued to grow until July 1999 when mortality of *C. virginica* approached 100% in all medium and high salinity sites. At that time mean shell height *of C. ariakensis* at low, medium and high salinity sites was respectively, 96, 125 and 140 mm. No growth was observed for either species during July to September 1999. Most of the growth occurred during fall 1998 and spring 1999.

Species and salinity regime had a significant effect on mean growth rate (Table 1A). Similar growth rates were observed for *C. virginica* at all salinities in contrast to increasing growth rates with increasing salinity observed for *C. ariakensis* (Fig 6). At low salinity sites, mean growth rate of *C. virginica* (1.1 mm mo^{-1}) was not significantly different than that of *C. ariakensis* (2.6 mm mo^{-1}). At medium salinity sites, mean growth rate of *C. virginica* (1.7 mm mo^{-1}) was significantly lower than that of *C. ariakensis* (4.9 mm mo^{-1}). At high salinity sites, mean growth rate of *C. virginica* (1.0 mm mo^{-1}) was also significantly lower than that of *C. ariakensis* (6.2 mm mo^{-1}). For *C. virginica*, growth rate did not differ significantly among salinity regimes. For *C. ariakensis*, however, growth rate at low salinity was significantly lower than that at medium and high salinity regimes (Table 1B).

Disease

At the beginning of the study, there was no *P. marinus* and a 4% prevalence of *H. nelsoni* in *C. virginica* and 12% prevalence of *P. marinus* and no *H. nelsoni* in *C. ariakensis* (Fig. 7). In October 1998, prevalence and weighted prevalence of *P. marinus* were significantly higher ($p < 0.0005$) in *C. virginica* than in *C. ariakensis*. In September 1999, when no live *C. virginica* remained at the medium salinity York River site, prevalence in *C. virginica* at all other sites was 100% whereas prevalence in *C. ariakensis* ranged from 0 to 75% and did not differ ($p > 0.250$) among salinity regimes (Fig. 7). Heavy infections were prevalent in *C. virginica* whereas only light infections were observed in *C. ariakensis* (Table 2).

Maximum prevalence of *H. nelsoni* (25%) was observed in *C. virginica* at the York River site in May 1999. *H. nelsoni* was also present in *C. virginica* at the low salinity Great Wicomico River site in September 1998 (4%), and at high salinity sites in October 1998 (4–8%) and May 1999 (4%). Intensity of *H. nelsoni* infections was light except for heavy infections found in oysters sampled from medium (1/132) and high salinity sites (1/157). No *H. nelsoni* was found in *C. ariakensis*. Other parasites observed in histological sections of *C. virginica* were the protozoan *Haplospo-*

TABLE 1.

Effects of species and salinity regime on mean growth rate.

C. ariakensis	Low salinity vs. high salinity	0.018
C. ariakensis	Medium salinity vs. high salinity	0.280

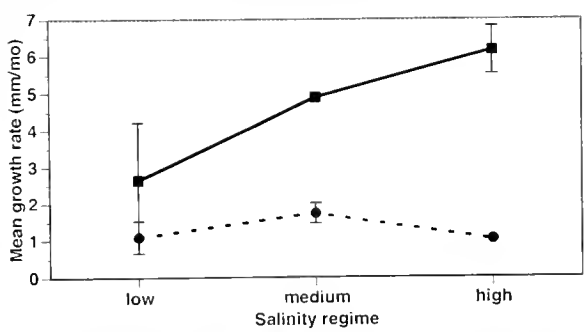

Figure 6. Interaction between oyster species and salinity on mean growth rate. Means of 2 sites (± SD). ● = *C. virginica*. ■ = *C. ariakensis*.

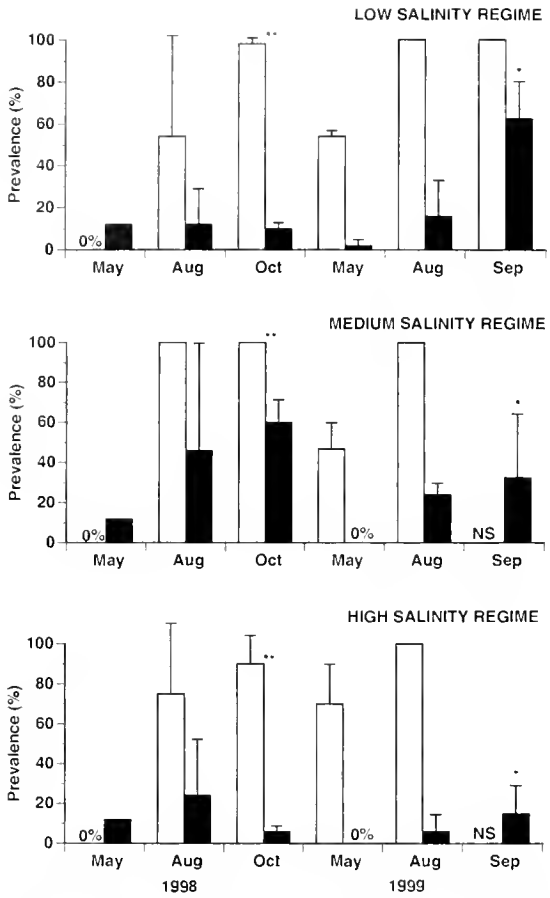

Figure 7. Mean prevalence of *P. marinus* by salinity regime (N = 2 sites, + SD), in samples of 25 oysters, from May 1998 to September 1999. Open bars = *C. virginica*. Solid bars = *C. ariakensis*. ** = Significant at $\alpha = 0.01$. * = Not significant at $\alpha = 0.05$. NS = Not sampled because no *C. virginica* remained.

ridium costale (SSO), present at high salinity sites, the trematode *Bucephalus* sp. and a chlamydia-like organism. None of these or other parasites were observed in *C. ariakensis*.

Condition

At low salinity sites, mean condition index in *C. virginica* and *C. ariakensis* were, 3.6 and 6.6, respectively, and means were not significantly different ($p = 0.121$). Similarly, there were no significant differences ($p = 0.121$) in mean body weights between species. At medium and high salinity, comparisons between species were not possible because no live *C. virginica* remained at those sites at the end of the experiment. For *C. ariakensis*, mean condition index at low, medium and high salinity, respectively, were 6.6, 5.3 and 9.7 and means were not significantly different ($p = 0.276$). Similarly, there were no significant differences ($p > 0.102$) between mean body weights among salinity regimes. The percentage of shell weight relative to whole oyster weight in *C. virginica* (62%) was similar to that in *C. ariakensis* at low, medium, or high salinity, respectively, 59, 61 and 65%.

Polydora

At low salinity sites, mean prevalence of *Polydora* spp. was 100% in both oyster species, and there was no significant difference in mean weighted prevalence between oyster species ($p = 0.121$). At medium and high salinity, comparisons between species were not possible because at the end of the experiment there were no live *C. virginica* at those sites. For *C. ariakensis*, there was a trend of decreasing prevalence with increasing salinity. Mean prevalence in *C. ariakensis* at low, medium and high salinity sites were, respectively, 100, 62 and 12%. However, ranked mean prevalence and weighted prevalence were not significantly different ($p = 0.156$) among salinity regimes.

Ploidy

The baseline sample revealed that prior to deployment 94% of the *C. ariakensis* in the lot were triploids. Individual certification assured that triploids were exclusively deployed in the field. During the course of the study, there were 62 individuals in which combinations of diploid and triploid cells (mosaics) were detected out of 1164 oysters examined (5.3%). The proportion of mosaics ranged from 0.0 to 13.8% depending on time and site (Table 3). The effect of time on mean percentage of mosaics was significant ($p = 0.002$). Mean percentage of mosaics increased significantly between the first sampling time and each subsequent sampling time ($p < 0.007$). After the initial sampling time, the percentage of mosaics did not differ significantly among the remaining sampling times ($p > 0.498$). Salinity regime had no effect on mean percentage of mosaics ($p = 0.128$). Examination of 39 mosaic individuals revealed that 10 were females, 23 were males, one was hermaphroditic, and five were undifferentiated.

DISCUSSION

Drought conditions and below normal Chesapeake Bay stream flow starting in fall 1998 resulted in increased salinity and epizootics of both *H. nelsoni* and *P. marinus* during 1999 (Ragone Calvo & Burreson 1999). High disease pressure prevailing in the region was associated with severe infections and high mortality in *C. virginica*, though not in *C. ariakensis*. After the first summer of disease exposure, more than 50% of *C. virginica* had died and prevalence of *P. marinus* at medium and high salinity sites was 100%. A year later when all *C. virginica* at medium and high salinity sites were dead, cumulative mortality at low salinity sites was 81% and prevalence of *P. marinus* was 100% with severe infections present. Maximum prevalence of *H. nelsoni* in *C. virginica* was 25% whereas no *H. nelsoni* was detected in *C. ariakensis*. Presence of *H. nelsoni* and intensification of *P. marinus* infections in *C. virginica* at the low salinity Great Wicomico site was undoubtedly favored by drought conditions resulting in salinity greater than 15% starting in fall 1998 and continuing into spring and summer 1999. Persistence of salinity greater than 15% during summer and fall is conducive to development of lethal *P. marinus* infections (Burreson and Ragone Calvo 1996). In comparison, maximum *P. marinus* prevalence in *C. ariakensis* reached 84%, but infections never exceeded light intensity and mortality remained low (13–16%). With the caveat that this study spanned only 15 months, *C. ariakensis* appears highly tolerant of the dominant parasitic diseases affecting Chesapeake Bay oysters.

A limitation of this study was that conditions were not identical for both species before the beginning of the experiment. Since *C. ariakensis* was quarantined for their first two years in land-based systems with limited inflow of raw York River water, long-term exposure to disease agents may have been reduced in relation to

TABLE 2.

that of *C. virginica* which was initially maintained in the water at a nearby location. Absence of *P. marinus* in the baseline sample of *C. virginica* collected in May 1998 does not preclude the possibility of sub-clinical infections. Given the low sensitivity of the standard diagnostic assay for detecting *P. marinus* infections during spring (Bushek et al. 1994, Burreson and Ragone Calvo 1996), it is likely that acquisition of infections occurred the prior summer but that overwintering infections were not detected the following spring.

Suminoe oysters tested in this study had comparable survival at all salinity regimes and similar growth rate at medium and high salinity regimes, in agreement with the wide salinity tolerance described for *C. ariakensis* in its native range (Guo et al. 1999). By the end of the experiment, when oysters were three years old, mean shell height of *C. ariakensis* at low, medium, and high salinity regimes was respectively 96, 125 and 140 mm. By comparison, in Zhanjiang Bay (annual salinity range = 7–30‰) average shell height of three-year-old Suminoe oysters is 100 mm (Cai et al. 1992).

In contrast to *C. gigas* in previous studies (e.g., Handley & Berquist 1997, Calvo et al. 1999), *C ariakensis* was not found to be adversely affected by *Polydora* spp. in this study. Mud worms were present in both *C. ariakensis* and *C. virginica*, but infestations were not severe and did not appear to affect growth or survival of either species. However, since the conditions that result in severe infestations are not clearly understood, we cannot dismiss the possibility that *C. ariakensis* might be susceptible to such infestations.

Results of the present investigation suggest that *C. ariakensis* is more adapted to Chesapeake Bay conditions than *C. gigas*. In a

Salinity codes: L = low (<15‰), M = medium (15–25‰), H = high (>25‰). Site codes: CNRV = Coan River, GWRV = Great Wicomico River, EARV = East River, YKRV = York River, BUBY = Burton Bay, BOBY = Bogues Bay. In parenthesis number of mosaics divided by number of oysters examined.

comparative study with *C. virginica* and *C. gigas* (Calvo et al. 1999), *C. gigas* exhibited high cumulative mortality (63%) at low salinity sites and growth rate was not greater than that of *C. virginica* within Chesapeake Bay. In contrast, *C. ariakensis* tested in this study had less than 16% cumulative mortality and greater growth rate than *C. virginica* within medium salinity sites in Chesapeake Bay. In grow-out trials with *C. gigas* and *C. ariakensis* using various culture methods at high salinity locations on the West Coast of USA, growth rate was the same for both oyster species. For example, *C. gigas* and *C. ariakensis* juveniles (mean shell height = 10 mm) planted directly on the bottom in Puget Sound, Washington, or suspended from floating rafts, in Yaquina Bay, Oregon, increased to 90–100 mm after 1 year of deployment during 1990 to 1991 (Langdon & Robinson 1996). A direct comparison between *C. gigas* and *C. ariakensis* is not available for the East Coast of USA. However, in this study and in Calvo et al. (1999), both species experienced significantly higher growth rate than the corresponding *C. virginica* control oysters at high salinity sites on the Atlantic Coast of Virginia.

The choice of oyster strain must be considered in the interpretation of results. *C. virginica* offspring from wild Mobjack Bay brood stock were employed in this study because they are a standard stock for aquaculture and because they were the only stock available with similar age, size and disease status *as C. ariakensis*. It is likely that a strain of *C. virginica* selected for disease resistance would more favorably compare to *C. ariakensis*. For example, DEBY, a strain of *C. virginica* that has been selectively bred by VIMS against *P. marinus* and *H. nelsoni* for four generations (Ragone Calvo et al. 1997), exhibited similar survival to that of *C. ariakensis* and higher survival, higher growth rate and lower disease susceptibility than that of unselected *C. virginica* from Mobjack Bay deployed at a site in the Great Wicomico River from June 1998 to May 1999 (G. Calvo unpublished data). Similarly, CROSBreed strains (Debrosse and Allen 1996) have been selected for dual resistance to both pathogens in the Mid-Atlantic. Use of disease resistant *C. virginica* strains could provide a more relevant comparison of native and non-native oyster performance for aquaculture.

To some extent, the fact that *C. ariakensis* were triploids may have allowed them to grow faster than diploid *C. virginica*. In general, reduced gametogenesis in triploids corresponds with improved somatic growth (Barber & Mann 1991). However, based on studies with *C. virginica and C. gigas*, ploidy effects alone are unlikely to account for reduced disease susceptibility and increased survival of *C. ariakensis*. Barber and Mann (1991) found that cohorts of diploid and triploid *C. virginica* had the same prevalence (96%) and similar intensity of *P. marinus* after 17 months of deployment at the York River, VA. Meyers et al. (1991) reported equal cumulative mortality for diploid and triploid *C. virginica* (100%) and lower cumulative mortality for diploid (25%) than triploid *C. gigas* (34%), after one year of challenge with *P. marinus*.

In summary, during the course of the study *C. ariakensis* performed better than *C. virginica* in Chesapeake Bay and the Atlantic Coast of Virginia. Wide salinity tolerance combined with low disease susceptibility was associated with high survival and high growth rate in *C. ariakensis*. In contrast, high disease susceptibility was associated with low survival and low growth rate in *C. virginica*.

As previously discussed for *C. gigas* (Calvo et al. 1999), a decision on whether *C. ariakensis* is, or is not, an appropriate species for use in these environments must include other factors beyond the scope of these field investigations. For example, international organizations have recommended that competent local authorities consider the ecological consequences of species introductions by evaluating the following: (1) the possibility that non-indigenous species may carry pests and pathogens into the new environment; (2) the potential relationship of the exotic species with native species; and (3) the potential range for establishment of the exotic species in the new environment. A cautious introduction of triploid *C. ariakensis* for aquaculture purposes following International Council for the Exploration of the Seas guidelines, as it is

currently being considered in Virginia, would minimize risks associated with factors enumerated above. Use of individually certified triploids in a closely monitored research setting allowed us to conduct the present study with minimum risks of unintentionally introducing reproductively capable *C. ariakensis* into the waters of Virginia. At the present time, however, there is no precedent for using triploids to control oyster populations at a commercial scale. In practice, implementation of such a strategy would require significant efforts directed at monitoring the reproductive status of deployed stocks over time, and at designing and enforcing strict quarantine regulations to avoid undesired release of reproductively capable stocks.

ACKNOWLEDGMENTS

We would like to thank Rita Crockett, Paige Ross and Francis O'Beirn for assistance in the field. Juanita Walker and Rita Crockett conducted disease diagnoses. Gregg DeBrosse and staff at Rutgers University produced triploid oysters. Ploidy analyses were conducted by Aimee Howe and Whitney Chandler. Wanda Cohen and Kay Stubbfield assisted with preparation of the figures. We would also like to acknowledge members of the oyster industry including Odus Cockrell, Lake Cowart Jr., Ken Kurkowski, Tommy Mason, John Register and John Vigliotta, for general support and access to field sites. VIMS contribution No. 2365.

DEVELOPMENT AND VERIFICATION OF A MODEL FOR THE POPULATION DYNAMICS OF THE PROTISTAN PARASITE, *PERKINSUS MARINUS*, WITHIN ITS HOST, THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*, IN CHESAPEAKE BAY

LISA M. RAGONE CALVO, RICHARD L. WETZEL, AND EUGENE M. BURRESON

School of Marine Science, Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, Virginia 23062

ABSTRACT A simulation model was developed to investigate the population dynamics of the protistan parasite, *Perkinsus marinus*, within its host, the eastern oyster, *Crassostrea virginica*. The main objective was to evaluate the relationship between *P. marinus* population dynamics and environmental conditions in order to predict the onset and termination of *P. marinus* epizootics in Chesapeake Bay oyster populations. Information derived from laboratory experiments and from direct field observations of *P. marinus* dynamics in the James River for the years 1990 to 1993 was utilized for model development. The individual-based model, which is driven by temperature and salinity, tracks the average within-host parasite density at a daily time step. The model was verified against monthly field observations of parasite abundance for the years 1994 to 1999 at three oyster bars located along a 0–20-ppt salinity gradient in the James River, Virginia. Simulated populations exhibited a distinct seasonal periodicity with annual density maximums and minimums occurring in October and May, respectively. Parasite abundance decreased in an upriver direction with decreasing salinity along the salinity gradient. Predicted parasite densities significantly correlated with actual observed densities at all three locations; however, the strength of the association decreased from bar to bar in an upriver direction. Predicted parasite abundance exhibited a dynamic steady state for all three oyster bars during the 6-year time series. Simulations run without the input of a midsummer transmission event resulted in a destabilization and extinction of the parasite from the oyster population located farthest upriver, but the parasite remained enzootic during the six year simulation at the two lower river stations. This suggests that a single transmission event may be sufficient for *P. marinus* to become enzootic in specific year classes of oyster populations located in moderate to high salinity areas, while periodic transmission events are required for the parasite to persist in low salinity areas. Simulation results suggest that fairly accurate quantitative predictions of *P. marinus* abundance can be made using *in situ* temperature and salinity data and a relatively simple model.

KEY WORDS: *Perkinsus*, model, disease, parasite, oyster, temperature, salinity

INTRODUCTION

Perkinsus marinus is a protistan parasite of the eastern oyster, *Crassostrea virginica*, that has significantly impacted oyster populations along the East Coast of the U.S. and in the Gulf of Mexico. Following its initial discovery in the Gulf of Mexico in 1947 (Mackin et al. 1950) *P. marinus* was soon found in the Chesapeake Bay (Andrews 1954). Prior to the mid 1980s the distribution of *P. marinus* within Chesapeake Bay was primarily restricted to moderate to high salinity areas located in the Bay and at the mouths of the major tributaries (Andrews 1988). However, the parasite's abundance dramatically increased in the late 1980s, and within a 4-year period it spread to nearly all oyster populations within the lower Bay (Burreson and Ragone Calvo 1996). Anomalous climatic conditions, consecutive drought years coincident with warm winters, are believed to be responsible for this extensive range expansion. While the historical restriction of *P. marinus* to high salinity areas suggests that over the long term the parasite cannot tolerate low salinity, the parasite remains enzootic in most low salinity areas despite the return to normal and even below normal salinities during the last decade. The persistence of the parasite in upper tributary oyster populations is particularly problematic, as these areas are the principle areas for seed production that historically has been the foundation of a significant private fishery. Critical to development of disease mitigation strategies and predictive capabilities is an understanding of how environmental factors effect *P. marinus* disease dynamics.

Many studies have focused on the importance of environmental factors in the maintenance of host-parasite equilibriums (Rohde 1982, Grenfell and Dobson 1995). The simplest conceptual model of disease dynamics is frequently drawn as three overlapping circles representing numerous host, parasite, and environmental factors. The overlapping area represents the interaction of the factors that ultimately leads to the domain of a particular disease. In a stabilized system, interactions between host, parasite, and environmental factors result in equilibrium between host and parasite populations (Anderson and May 1978). Alterations in conditions affecting any of the three components of the system can potentially result in destabilization resulting in parasite extinction or the initiation of an epizootic. Gaining an understanding of how environmental factors effect host-parasite relationships is often a challenge, but such an understanding is essential for predicting the onset and abatement of disease epizootics.

In the case of *P. marinus*, temperature and salinity have been identified as the most important environmental factors affecting its interactions with its host *C. virginica* (Andrews 1988, Burreson and Ragone Calvo 1996). Temperature appears to be the most important factor affecting the large-scale geographic distribution of the parasite (Quick and Mackin 1971, Burreson and Ragone Calvo 1996, Ford 1996) and is primarily responsible for the seasonal periodicity of *P. marinus* observed within a particular geographic area. In the Chesapeake Bay *P. marinus* exhibits a distinct seasonal periodicity in which prevalence and intensity increases during the summer months to annual maximums in September and October and then decreases during the late fall, winter, and early spring to annual minimums in April and May. The relative abundance of the parasite within an estuary at any particular time is largely influenced by salinity. Generally, *P. marinus* infections

remain light in intensity and no oyster mortality results if salinity is consistently less than 9 ppt, while high intensity infections and associated oyster mortality often occur in areas where salinities are greater than 12–15 ppt (Ragone and Burreson 1993, Burreson and Ragone Calvo 1996).

Although the independent effects of temperature and salinity on *P. marinus* have been extensively studied, fewer studies have addressed the importance of the interaction of temperature and salinity, or the interaction of temperature and salinity with other factors, in triggering and maintaining *P. marinus* epizootics. Based on simulations using an energetics-based model of *P. marinus* and *C. virginica* population dynamics in the Gulf of Mexico, Powell et al. (1996) concluded that changes in temperature and salinity alone do not trigger epizootics. Their simulations indicated that some other factor, such as reduced food supply or reduced recruitment rates, must occur prior to or coincidentally with high salinity or high temperature conditions for an epizootic to be triggered.

In the present study, a mathematical model was developed to synthesize the results of various field and laboratory studies that have been conducted in our laboratory during the last 10 years with a focus of gaining a better understanding of the interactive effect of temperature and salinity on *P. marinus* disease dynamics. We present the results of initial efforts to integrate, via an individual-based simulation model, temperature and salinity control of within-host population dynamics of *P. marinus* in the lower Chesapeake Bay.

METHODS

General Model Description

The *P. marinus* model was developed using the program STELLA II (Version 3.04, High Performance Systems Inc., Hanover, NH) on a Power Macintosh computer. The model is an individual-based model that simulates the transmission, growth and death of parasite cells within its host, the eastern oyster. Within-host parasite abundance, the only state variable, is tracked through time using a daily time step. Within-host parasite abundance represents the average abundance for a particular population of one year and older oysters. The model has four main components: parasite growth, parasite transmission, parasite mortality, and parasite loss via host death (Fig. 1). Both parasite division and parasite mortality are forced by temperature and salinity conditions. The basic model equation is (Eq. 1):

$$dP/dt = P(P_G + P_T - P_M - P_L) \quad (1)$$

where P = parasite density (cells (g wet wt)$^{-1}$), P_G = parasite cell growth, P_T = parasite transmission, P_M = parasite mortality, and P_L = parasite loss via host death (Table 1).

Perkinsus marinus Growth

Estimates of *P. marinus* growth rates or doubling times and the effects of temperature, salinity, and cell density on *P. marinus* growth are limited. Doubling time estimates derived from *in vivo* studies conducted with oysters from the Gulf of Mexico range from 7–60 hours (Saunders et al. 1993). Ford et al. (1999) found *in vivo* parasite doubling times in Delaware Bay oysters held under experimental conditions to range from 3–23 days. *In vitro* doubling times of cultured *P. marinus* have been reported to range from 13–24 hours (Dungan and Hamilton 1995, Gauthier and Vasta 1995, La Peyre 1996). Reported doubling times from both *in vivo* and *in vitro* studies are based on a variety of techniques and primarily represent optimal conditions, i.e., temperatures >25°C, high salinity (>17 ppt), and/or low initial cell densities. Alteration of any of these factors will result in changes in *P. marinus* growth rates. Saunders et al. (1993) and Ford et al. (1999) found that cell densities of greater than 10^4 to 5×10^4 per g wet wt oyster^{-1} significantly reduced cell division rate, suggesting that a density dependent feedback mechanism is operative. Decreases in temperature and salinity of *in vitro* culture conditions also resulted in slower *P. marinus* growth rates (Gauthier and Vasta 1995, Dungan and Hamilton 1995, La Peyre 1996). Likewise, investigations of *P. marinus* activity in nature and in *in vivo* laboratory experiments have demonstrated the pronounced effect of temperature and salinity on *P. marinus* infection progression in oysters. Field obser-

Feedbacks		
Parasite density dependent self-limitation of $P_{dis}(t)$	$FB_p(t)$	
Parameters		
Parasite growth threshold density	A_p	10,000 cells (g wet wt)$^{-1}$ d^{-1}
Parasite maximum density	G_p	2×10^6 cells (g wet wt)$^{-1}$ d^{-1}
Parasite division rate	μd	d^{-1}
Parasite transmission rate as function of salinity	μt_{sal}	at S >15 = 1000 cells d^{-1} at 15 > S > 12 = 500 cells d^{-1} at 12 > S > 9 = 100 cells d^{-1} at 9 > S > 6 = 50 cells d^{-1} at S < 6 = 0 cells d^{-1}
Parasite mortality rate as function of salinity	μm_{sal}	at S > 12 = 0.0175 d^{-1} at 12 ≥ S ≥ 8 = 0.02 d^{-1} at 8 > S ≥ 3 = 0.0175 d^{-1} at S < 3 = 0.006 d^{-1}
Parasite loss via host death	μl	at P(t) >100,000 = 0.50 d^{-1}
Initial condition of state variable		
Parasite (WS Calibration)	P_0	801 cells (g wet wt)$^{-1}$
Parasite (WS Validation)	P_0	3927 cells (g wet wt)$^{-1}$
Parasite (HH)	P_0	537 cells (g wet wt)$^{-1}$
Parasite (DWS)	P_0	135 cells (g wet wt)$^{-1}$

vations indicate that parasite proliferation occurs at temperatures above 20°C (Andrews and Ray 1988). This observation has been supported by laboratory experiments in which infection progression was followed in artificially infected oysters held at 10, 15, 20, and 25°C (Chu and La Peyre 1993). Chu and La Peyre (1993) reported that only those oysters held at 20 and 25°C had moderate to heavy infections at the termination of the 7-wk experiment. Similarly, infection progression in oysters maintained in the laboratory at 25°C for a 6-wk period was delayed at 12 ppt and ceased at salinities below 9 ppt (Ragone and Burreson 1993).

In the model, parasite cell growth, the increase in parasite density as a result of cell division, is dependent on salinity, temperature, and parasite density. The model equation for cell growth was derived as:

$$P_G = P * \mu d * (1-((P-Ap)/(Gp-Ap)) \quad (2)$$

where P_G = parasite growth, P = parasite density (cells (g wet wt)$^{-1}$), μd = parasite division rate (d^{-1}), Ap = threshold parasite density (cells (g wet wt)$^{-1}$), and Gp = maximum parasite density (cells (g wet wt)$^{-1}$).

Since *P. marinus* growth has been demonstrated to be density dependent (Saunders et al. 1993, La Peyre 1996) a nonlinear density dependent negative feedback mechanism was incorporated into the equation for cell growth. Maximum density (Gp) was set at 2,000,000 parasites (g wet wt)$^{-1}$. This value was based on maximum *P. marinus* densities observed in oysters sampled from Wreck Shoal, James River, Virginia during a study conducted from 1993 to 1994 (Oliver et al. 1998). The maximum density represents the density at which space and or nutrients are so limited that parasite division no longer occurs. The threshold density (Ap), the density above which parasite growth is inhibited by intra specific competition for space and or nutrients was set at 10,000 (g wet wt)$^{-1}$. This value was also inferred from field data and represents an approximation of cell abundance in an oyster having a moderate intensity infection.

Parasite division rate (μd) is dependent on temperature and salinity. Field observations indicate that infections progress at temperatures exceeding 20°C (Burreson and Ragone Calvo 1996). On this basis, parasite division only occurs at temperatures exceeding 20°C. Temperature control follows a standard exponential form using a Q_{10} of 2.0 to calculate cell division at temperatures greater than 20°.

Initially the model was run using parasite division rates that were taken from the literature; however, initial model simulations resulted in unnatural population dynamics. Hence an alternative estimation of *P. marinus* division rate was derived. As an alternative, site specific division rates were derived from field data and laboratory studies. Since 1987, the Virginia Institute of Marine Science has been conducting an intensive survey program to monitor *P. marinus* prevalence and intensity at three oyster bars located in the upper the James River, Virginia. Oysters (n = 25) have been sampled monthly from Wreck Shoal (WS), Horsehead Bar (HH),

and Deepwater Shoal (DWS) (Burreson and Ragone Calvo 1996) (Fig. 2). These oyster bars are located along a salinity gradient with average salinities for the years 1987 to 1994 of 14 ppt at WS, 9 ppt at HH, and 7 ppt at DWS (Burreson and Ragone Calvo 1996). Sampled oysters were examined for *P. marinus* using a semi-quantitative assay described by Ray (1954). Using this method infections are categorized according to intensity and assigned a value from 1–7 for light to heavy intensities, respectively. The weighted prevalence (average infection intensity) can then be calculated yielding a single value that describes the average parasite cell density (Mackin 1962). For the purpose of calculating weighted prevalence for the VIMS data, infection intensities were assigned ranks as follows: 2 for light intensity, 4 for moderate intensity and 6 for heavy intensity. More recently a quantitative assay was developed for determining total parasite density in whole oysters (Choi et al. 1989). Whole oyster parasite densities were found to significantly correlate with Ray assay tissue ranks (Choi et al. 1989, Bushek et al. 1994). The regression equation presented by Bushek et al. (1994) ($y = 0.176 - 0.463x + 0.205x^2$, where y = log 10 *P. marinus* cells (g wet tissue weight)$^{-1}$ and x = infection rank) was used to convert VIMS oyster disease survey data from weighted prevalence to average parasite density (Fig. 3). Cell division rates were then determined using the calculated parasite densities from each station for the months May to June and June to July 1990 to 1993. During these months temperature is rising above 20°C and cell densities are generally low, so the rates determined are appropriate estimates for an initial division rate. Division rates were calculated using the natural log formula for population growth. The average division rates were respectively 0.009, 0.014, and 0.042 divisions d^{-1} at DWS, HH, and WS. Average salinity at the sites for the same period was 4.6 ppt at DWS, 7.1 ppt at HH, and 11.7 ppt at WS. Using data from a laboratory study presented by Ragone and Burreson (1993), the rate of division at 20 ppt was estimated to be 0.06 d^{-1}. A significant correlation was observed between salinity and the estimated division rates ($P = 0.013$, $r^2 = 0.973$), and the resultant regression equation ($y = -0.009 + 0.004x$, where x = salinity) was used as a first approximation to incorporate salinity control on μd into the

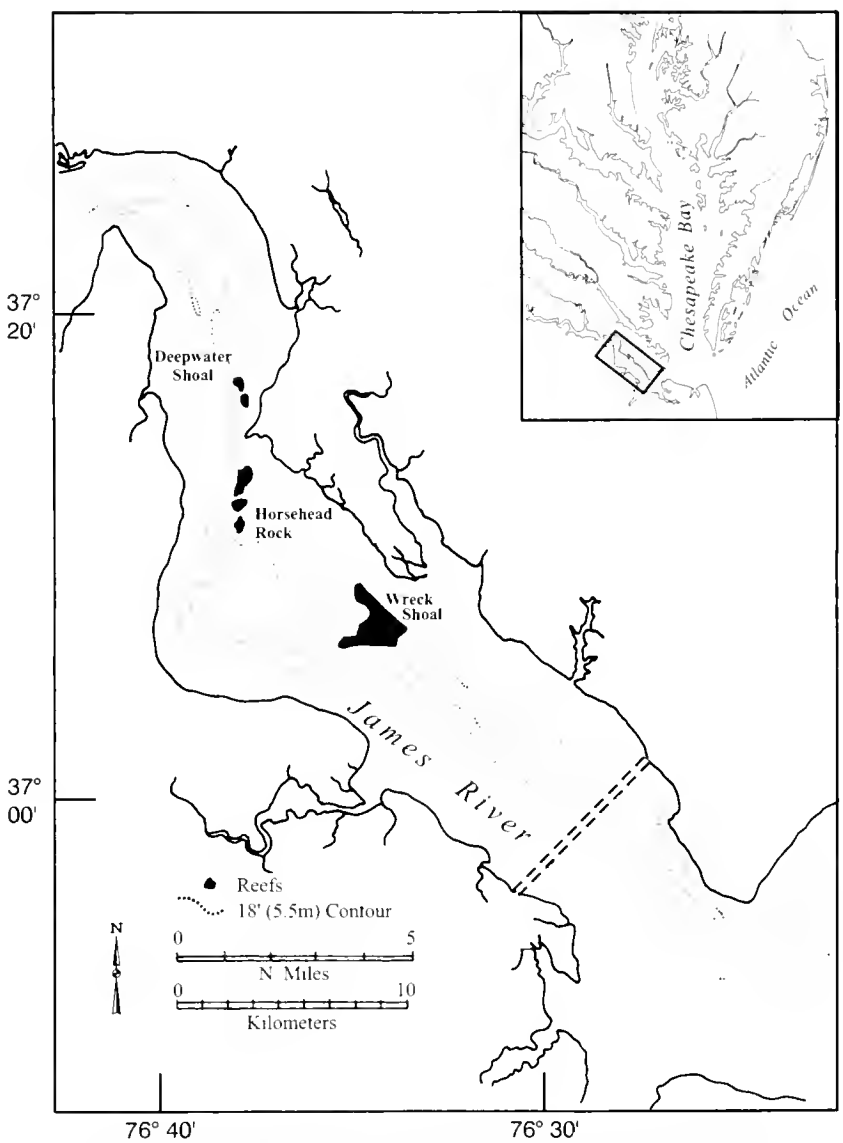

Figure 2. James River, Virginia oyster disease monitoring sampling sites.

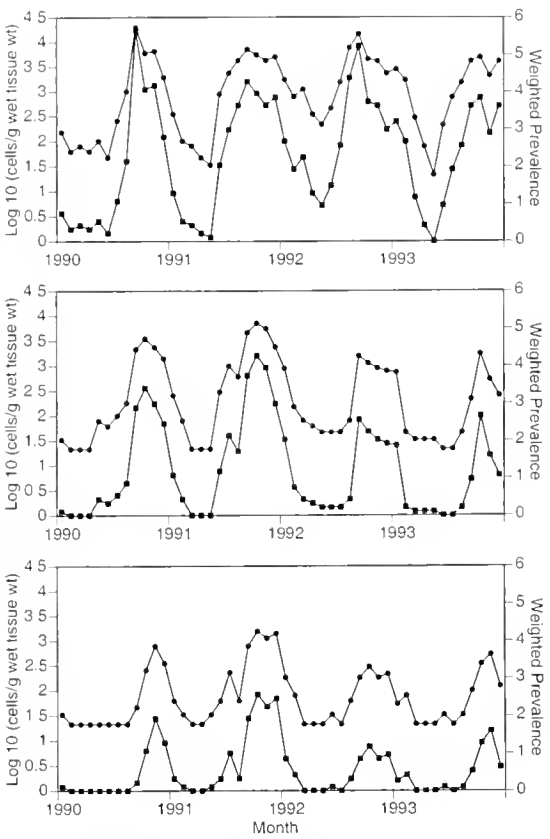

Figure 3. Conversion of *P. marinus* weighted prevalence (squares) to cells (g wet tissue wt)$^{-1}$ (circles). Converted 1990 to 1993 data is shown for three James River, Virginia oyster bars—Wreck Shoal (top), Horsehead (middle) and Deepwater Shoal (bottom). Conversions were calculated using equation presented by Bushek et al. 1994.

model. Sensitivity testing lead to refinement of this relationship and the final equation for parasite division was derived as:

$$\mu d\,(t) = (-0.009 + 0.0035 * S(t))\, e^{a\,(T(t)-20)} \qquad (3)$$

where $\mu d(t)$ = specific rate of parasite division (d^{-1}), a = Q10 conversion (0.06931), S = salinity (ppt), and T = temperature (°C).

Perkinsus marinus Death

Perkinsus marinus cell death is likely mediated by host-defense mechanisms and environmental conditions, but the processes involved are poorly understood. *Perkinsus marinus* is readily phagocytized by host hemocytes; however, it appears that these putative immunocytes do not readily destroy the parasite as observations of intrahemocytic destruction of *P. marinus* are limited (Anderson et al. 1995). Investigations on other mechanisms of the oyster immune system, including antimicrobial molecules, agglutinins, and lysins, have been conducted in relation to *P. marinus* but none have been demonstrated to be an effective control. Given the insufficient knowledge of the role of host defense in controlling *P. marinus*, no attempt was made to parameterize host-mediated cell death separately from other processes causing cell death. Instead, our approach was to characterize infection regression in general based on literature and on our own field studies. In the Chesapeake Bay, *P. marinus* abundance typically declines dramatically during the winter and spring. Andrews (1988) hypothesized that at temperatures less than about 20°C there is a physiological balance between *P. marinus* and the oyster, and host defense activities are favored over parasite proliferation. While it is clear that *P. marinus* multiplication is inhibited at low temperature (Chu and Greene 1989, Chu and La Peyre 1993, Chu and Volety 1997), it remains unclear as to whether host defense activities become favored within a particular temperature regime. Ford et al. (1999) examined Andrews' hypothesis by following *P. marinus* burdens in oysters maintained at 15°C and two different salinity treatments (12–14 ppt and 25–28 ppt) and found that oysters were unable to eliminate infections during the 11 week experiment. In contrast, they found that infections progressed during the study. While this study suggests that 15°C is not an optimum temperature for *P. marinus* elimination, it does not negate the possibility that a temperature lower than 15°C may be optimal for parasite elimination.

In an effort to gain a better understanding of *P. marinus* infection regression dynamics, monthly parasite elimination rates were determined from our 1990 to 1993 James River oyster disease survey data and examined in relation to temperature and salinity. Monthly *P. marinus* weighted prevalences were converted to parasite densities as described above, and parasite mortality rates were subsequently determined for the months October to November, November to December, December to January, January to February, and February to March. The parasite mortality rates were then examined in relation to average monthly temperature and salinity. Parasite mortality rate significantly correlated with temperature, increasing with decreasing temperature ($P < 0.0001$, $r^2 = 0.241$). On average the highest parasite mortality rates were observed at the higher salinity station, Wreck Shoal, than upriver at the lower salinity stations Horsehead Rock and Deepwater Shoal. Average salinities for Wreck Shoal, Horsehead Bar, and Deepwater Shoal for the months November through April 1990 to 1993 were respectively 12, 6, and 3 ppt.

Based on the field results described above, the model equation for parasite mortality was derived with both temperature and salinity controls. Since parasite mortality rates were higher at Wreck Shoal than at the two upriver stations, parasite mortality was set to optimally occur at 8 to 12 ppt. Within this salinity range the parasite is assumed to be relatively inactive while salinity is still high enough for host defense mechanisms to be operative. Base parasite mortality rates were altered with the highest rate occurring at 8–12 ppt, while slightly lower rates were set for >12 ppt and for 3–8 ppt. At <3 ppt, host physiological processes are assumed to be inactive, so parasite mortality rate was set extremely low. In the model parasite mortality occurs only at temperatures <18°C and >3°C. Between 18 and 3°C, temperature control of parasite mortality follows a standard exponential decay form using a Q10 of 2.0. Base rates were derived through sensitivity analysis of values within the range of those observed in the field. The equation for parasite mortality was derived as:

$$P_M = P * \mu m \qquad (4)$$

where P = parasite density (cells (g wet wt)$^{-1}$) and μm = specific parasite mortality rate (d^{-1}),

Such that:

$$\mu m\,(t) = \mu m_{sal} e^{a\,(18-T(t))} \qquad (5)$$

where $\mu m(t)$ = specific rate of parasite mortality; μm_{sal} = parasite mortality rate (d^{-1}) as a function of salinity where:

$\mu mt_{sal} = 0.0175$ at $S > 12$ and $8 > 3$ ppt,

$= 0.02$ at $12 \geq S \geq 8$ ppt and

$a = 0.003$ at $S < 3$ ppt;

a = Q10 conversion (0.06931), S = salinity (ppt) and T = temperature (°C).

Perkinsus marinus Transmission

Although it is well documented that transmission of *P. marinus* is direct from oyster to oyster, the natural dynamics of transmission are poorly understood. The prevailing conceptual model is that transmission occurs during periods of high oyster mortality as infective *P. marinus* cells are disseminated upon death and decomposition of infected oysters (Andrews 1988). Flow cytometric techniques have been developed that allow quantification of disseminated *P. marinus*-like cells in the water column (Roberson et al. 1993). This technique was employed to systematically examine the seasonality of *P. marinus* infection acquisition in oysters in relation to water column abundance of *P. marinus*-like cells, oyster mortality, and temperature (Ragone Calvo et al. 1995). Distinct peaks of all three parameters occurred during the month of August, following maximal summer temperatures (Fig. 4) (Ragone Calvo et al. 1995). Water column *P. marinus*-like cell abundance, infection acquisition, and oyster mortality decreased from summer maximums as temperatures decreased in September and October and remained at "wintertime" low levels from October through the termination of the study in March. These results support the currently accepted hypothesis that infective stages of *P. marinus* originate primarily from dying oysters and are most abundant in August.

Simulations were run both with and without transmission of parasites. When transmission is incorporated in the model, it occurs as a single event occurring once each year on Julian day 218. This timing corresponds with the early August transmission event observed by Ragone Calvo et al. (1995). In the model, the number of parasite cells transmitted is a function of salinity such that:

$$P_T = \mu t_{sal} \tag{6}$$

where μt_{sal} = the specific rate of parasite transmission (d^{-1}) as a function of salinity and has default values of:

1000 cells at $S > 15$ ppt,

500 cells at $15 > S > 12$ ppt,

100 cells at $12 > S > 9$,

50 cells at $9 > S > 6$ ppt and

0 cells at $S < 6$ ppt.

Salinity control of transmission is assumed to occur for two reasons: (1) infective cells are likely diluted by river discharge and (2) *P. marinus* infection levels and associated oyster deaths are limited in lower salinity areas. Clearly, this is an oversimplification of a process that is quite complex, but for lack of information it is a first approximation for model development and simulation analysis.

Parasite Loss via Host Death

It is assumed that the average *P. marinus* within-host abundance in any oyster population decreases as a result of the death of heavily infected hosts. This loss of parasites is incorporated into the model by the equation:

$$P_L = P(t) * \mu l \tag{7}$$

where μl = parasite loss rate (d^{-1}) and where $\mu l = 0.50$ at $P(t) > 100{,}000$ cells(g wet wt)$^{-1}$ and 0.00 at $P(t) < 100{,}000$ cells(g wet wt)$^{-1}$.

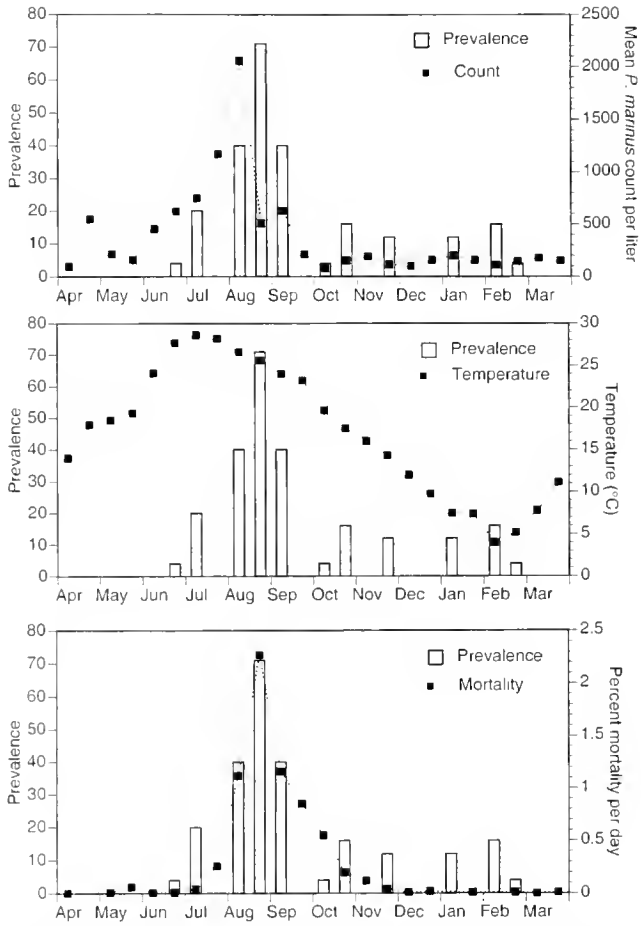

Figure 4. Results of *P. marinus* transmission study conducted by Ragone Calvo et al. (1995). *Perkinsus marinus* infection acquisition (prevalence) by previously uninfected sentinel oysters in relation to biweekly mean water column cell counts (top), biweekly mean temperature (middle), and oyster mortality rate (bottom) in the lower York River, Virginia.

Environmental Parameters

The model is driven by two environmental factors: temperature and salinity. The water temperature data series for both the model development data set (1990 to 1993) and the validation data set (1994 to 1999) were derived from a continuous monitor at the VIMS pier in the lower York River. Measurements were recorded at 6-min intervals; however, only daily means are utilized in the model. The salinity time series for Deepwater Shoal, Horsehead Rock, and Wreck Shoal were compiled from three sources—biweekly measurements taken by the State Water Control Board, weekly measurements (May through October only) taken in conjunction with the VIMS shellstring survey, and monthly measurements taken in conjunction with the VIMS oyster disease monitoring program. Monthly means for each of the three stations were

determined from the pooled data sets for incorporation into the model.

Model Calibration and Validation

As described above, since 1987, the Virginia Institute of Marine Science has been conducting an intensive survey program to monitor *P. marinus* prevalence and intensity at three oyster bars located along a salinity gradient in the upper the James River, Virginia. Separate portions of this data set were utilized for model calibration and validation. Data collected from Wreck Shoal during 1990 to 1993 was utilized for model calibration. The model was subsequently validated using 1994 to 1999 time series for Wreck Shoal, Horsehead Rock, and Deepwater Shoal. Since the monthly determinations of *P. marinus* prevalence and intensity were determined using Ray's fluid thioglycollate tissue assays (Ray 1954), which is only semi-quantitative, it was first necessary to convert the data to a quantitative format. This was accomplished using a conversion equation presented by Bushek et al. (1994) as described above. The conversion yielded average within-host abundances of *P. marinus* cells per gram wet tissue weight. Initial conditions for both model development and validation simulations were set to correspond to the actual *P. marinus* abundances that were observed in the first month of the time series (Table 1). *In vivo* parasite abundance was tracked at a daily time step.

Statistical Analysis

The significance of the association between predicted and actual *P. marinus* abundance was examined by linear regression using Abacus Concepts, Statview (Abacus Concepts, Inc., Berkeley, CA, 1992). Additionally, sensitivity analysis was conducted to examine the effect of variation of model parameters (μd, μm, μt, and μl) and input variables (S and T) on model performance. The rate parameters and input variables were systematically varied by ± 20% and sensitivity effects were assessed by calculating the residual, or root, mean square deviation (RMS) (Buzzelli et al. 1999) between the nominal model and the test cases, such that:

$$RMS = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(P_i - O_i)^2}$$

where P_i = model nominal (predicted) value, O_i = sensitivity test case value, and n = number of daily time steps in the six year simulation (n = 2190).

Differences between comparisons were normalized by calculating percent errors where the average RMS for the +20% and −20% test conditions is divided by the mean of O_i. The model is considered to be sensitive to parameters that yield % errors greater than 10%.

RESULTS

Model Calibration

The simulated within-host abundance of *P. marinus* using a lower York River water temperature time series and Wreck Shoal, James River salinity time series for the years 1990 to 1993 significantly correlated with actual observed abundance ($P < 0.0001$, $r^2 = 0.761$) (Fig. 5). The simulation generated a dynamic steady state in which parasite abundance exhibited a distinct seasonal periodicity with maximum abundance occurring in mid-August through mid-September following peak summer temperatures.

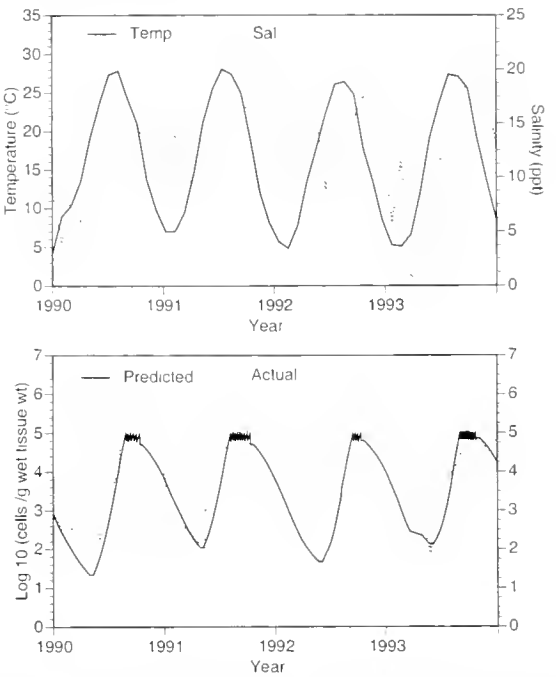

Figure 5. Simulation results for model development-time series, Wreck Shoal, James River, Virginia 1990 to 1993, showing temperature and salinity time series (top) and predicted versus actual observed *P. marinus* abundances (bottom).

Maximum cell division rates ranged from 0.09 to 0.11 divisions d^{-1}. These rates resulted in generation times from 6–7 days. Parasite abundance declined as temperature decreased during the fall and winter months, and minimums were observed from late April to mid-May. Deviations of the predicted abundance from the actual abundance were most evident in year one and year three at times of minimum and maximum abundance. In each year of the time series maximum *P. marinus* abundance exceeded 100,000 cells (g wet wt)$^{-1}$ and hence decreases in abundance associated with host death were observed. The occurrence of parasite loss due to host death appears as very short term oscillations in the simulation; population mean abundance is depressed due to parasite loss and then immediately increases as a result of parasite growth. Hence, the duration of the short-term oscillations yields information on the relative extent of parasite-associated host mortality from year to year.

The 1990 to 1993 environmental time series was quite variable. Annual salinity minimums and maximums ranged from 0.5 to 9.4 ppt and 15.7 to 19.1 ppt, respectively, while annual temperature minimums and maximums ranged from 4.2–6.9°C and 26.4–28.0°C, respectively (Fig. 5).

Model Validation

The model was validated using a lower York River temperature time series and site-specific salinity time series for Deepwater Shoal, Horsehead Bar, and Wreck Shoal, James River, Virginia for the years 1994 to 1999. The environmental time series included a broad range of conditions with unusually warm years (1997, 1998) and cold years (1996), as well as wet (1996, 1998) and dry years (1995, 1999). Annual temperature minimums ranged from 2.7 to 7.7°C, and annual temperature maximums ranged from 26.7 to 28.4°C (Figs. 6–8). Annual salinity minimums ranged from 2.0 to

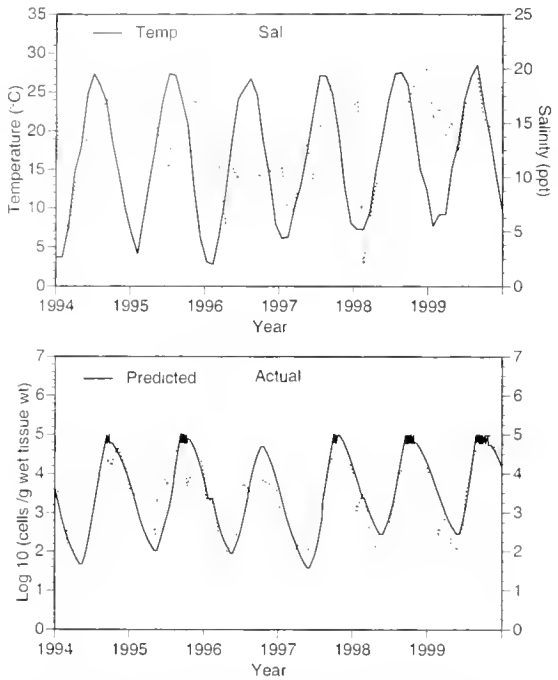

Figure 6. Validation model simulation results for Wreck Shoal, James River, Virginia 1994 to 1999 showing temperature and salinity time series (top) and predicted versus actual observed *P. marinus* abundances (bottom).

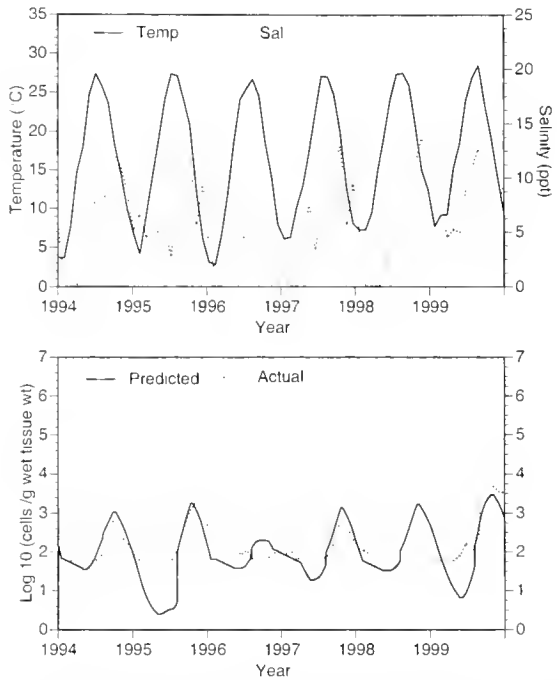

Figure 8. Validation model simulation results for Deepwater Shoal, James River, Virginia 1994 to 1999 showing temperature and salinity time series (top) and predicted versus actual observed *P. marinus* abundances (bottom).

12.5 ppt at WS, 0 to 5.5 ppt at HH, and 0 to 4.5 at DWS, while annual maximums in salinity ranged from 14.1 to 20.5 at WS, 7.3 to 16.0 at HH, and 6.2 to 13.7 at DWS (Figs. 6–8).

Predicted *P. marinus* abundance significantly correlated with actual observed abundance for all three sites; however, the strength of the correlation decreased in an upriver direction ($P < 0.0001$, $r^2 = 0.724$ at WS, 0.598 at HH, and 0.450 at DWS) (Figs. 6–8). As observed with the 1990 to 1993 time series simulations, simulations for all three oyster populations generated a dynamic steady state in which parasite abundance exhibited a distinct seasonal periodicity. Parasite abundance exponentially increased during the summer months reaching an annual peak in abundance between mid-September and mid-October. As temperature declined below 18°C during the fall, parasite abundance decreased. This decrease in parasite number continued through the winter and early spring reaching an annual minimum between late April and mid-May. Both the magnitude and timing of annual maximum parasite abundance varied both with respect to year and location. Annual abundance maximums were higher and generally occurred earlier at WS (Fig. 6) than at HH (Fig. 7) and at HH than at DWS (Fig. 8).

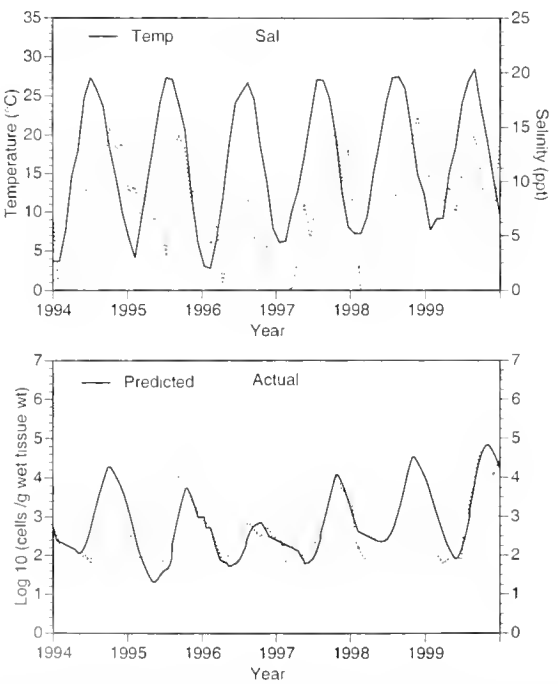

Figure 7. Validation model simulation results for Horsehead Shoal, James River, Virginia 1994 to 1999 showing temperature and salinity time series (top) and predicted versus actual observed *P. marinus* abundances (bottom).

The predicted annual periodicity of *P. marinus* abundance, particularly for WS, closely followed actual observed infection intensity and prevalence patterns in upper James River oyster populations. *Perkinsus marinus* abundance in the upper James River is typically highest during the months of September and October and lowest in May. Parasite abundance decreases in an upriver direction from WS to DWS and abundance peaks later in the upper river locations. For WS predicted annual averages, maximums and minimums in parasite abundance were always the same order of magnitude as actual observed abundance; however, at HH and DWS differences greater than 1 order of magnitude were sometimes observed. Specifically, at HH, 1998 predicted maximum abundance exceeded actual observed abundance by 1.03 orders of magnitude, and at DWS 1995 predicted minimum abundance were 1.38 orders of magnitude lower than actual observed values, and 1998 predicted abundance maximums exceeded actual abundance by 1 order of magnitude.

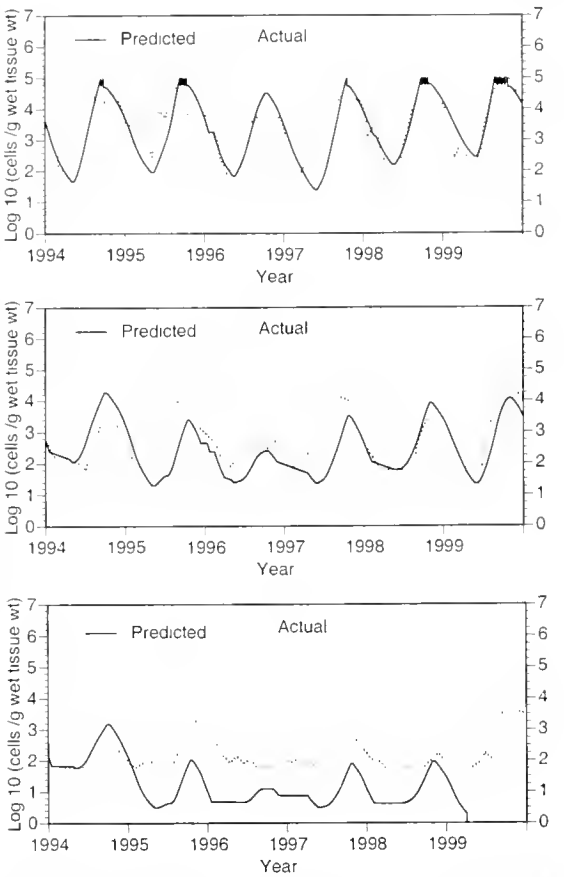

Figure 9. Model simulation results of predicted and actual observed *P. marinus* abundance for Wreck Shoal (top), Horsehead Rock (middle), and Deepwater Shoal (bottom) for the period 1994 to 1999 for condition in which annual transmission input is eliminated from model.

In the model *P. marinus* proliferation occurred only at temperatures greater than or equal to 20°C at salinity greater than 0 ppt. On average, these conditions were met, and cell division occurred 139 days per year. The number of days in which the parasite was active decreased in an upriver direction and inter annual variability was relatively high with the annual number of proliferation days ranging from 135–154 days at WS, 135–150 days at HH, and 90–150 days at DWS. Overall predicted mean, minimum and maximum cell division rates (d^{-1}) were respectively: 0.061 (± 0.017 SD), 0.023, and 0.104 at WS; 0.034 (± 0.017 SD), 0.0006, 0.073 at HH; and 0.026 (± 0.014 SD), 0.0001, 0.063 at DWS. The predicted division rates correspond to generation times ranging from 6 to 34 days.

Parasite death as incorporated into the model was modulated by both temperature and salinity. On average, parasite regression occurred 196 days per year. Predicted parasite mortality rates ranged from 0.006 to 0.057 d^{-1}. Average predicted parasite mortality rates (d^{-1}) were respectively 0.031, 0.023, and 0.021 at WS, HH, and DWS. Overall parasite regression rates were higher at WS than at HH and DWS; however, there were exceptions as both HH and DWS had higher parasite mortality rates than WS in 1995 and 1999.

Parasite loss via host cell death was incorporated into the model such that the state variable, parasite abundance, was reduced by 50% at parasite densities greater than 100,000 (g wet wt)$^{-1}$. At WS, parasite loss was an important regulator of parasite abundance and is evident in the simulations as high frequency short-term high oscillations in parasite abundance occurring coincidentally with summer abundance maximums. The periodicity of parasite cell loss due to host death at WS varied from year to year, being most apparent in 1999 and absent in 1996. Parasite burdens did not escalate to lethal levels at HH and DWS; hence loss via host death did not impact parasite abundance at these sites.

Parasite transmission was incorporated into the model as a single annual pulse of parasite cells into the host. The magnitude of the pulse is dependent on ambient salinity at the time. The number of cells transmitted ranged from 50 at salinity between 6 and 9 ppt to 1000 at salinity greater than 15 ppt. In the simulations transmission occurred in all years at all sites and varied from 50 to 100 at DWS, 50 to 500 at HH, and 500 to 1000 at WS.

In order to examine the relative importance of annual transmission events in maintaining *P. marinus* epizootics, the transmission component was eliminated from the model and simulations were run without the occurrence of an annual transmission event. The modified model produced simulations for WS and HH in which parasite abundance remained in a dynamic steady state (Fig. 9). Predicted *P. marinus* abundance for WS and HH correlated with actual observed abundance ($P < 0.001$, $r^2 = 0.709$ at WS, $r^2 = 0.444$ at HH); however, the correlation was not as strong as that produced by the original model. In contrast, *P. marinus* abundance for DWS did not maintain a dynamic steady state and parasite abundance gradually decreased over time with parasite extinction occurring in year 6 (Fig. 9).

Sensitivity Analysis

Sensitivity analysis was conducted in order to evaluate how relative changes in model parameters would effect model performance. The sensitivity of the model to key rate parameters varied with sampling location. For Wreck Shoal, the model was sensitive

TABLE 2.

* Sensitive parameters.

to only one rate parameter, parasite mortality, μm. A 20% change in μm resulted in a 13% error (Table 2). When model performance was assessed using the time series for Horsehead Rock and Deepwater Shoal, the model was sensitive to both parasite division rate and mortality rate and percent errors ranged from 16 to 23% (Table 2). The model was also very sensitive to temperature and salinity. Percent errors associated with a 20% change in temperature were 43% for Wreck Shoal, 66% at Horsehead Rock, and 59% at Deepwater Shoal. Salinity had a lesser effect than temperature. For Wreck Shoal, the model was not sensitive to 20% change in salinity, but for Horsehead Rock and Deepwater Shoal percent errors were relatively high, 30% and 49% respectively.

DISCUSSION

The model as currently constructed is simple but provides realistic population simulations for *P. marinus* within its host *C. virginica*. The dynamics of the populations described by these simulations reflects the importance of temperature and salinity in regulating *P. marinus* population dynamics. The annual cycle of parasite abundance exhibited a strong seasonal periodicity reflecting the controlling influence of temperature. As observed in nature (Andrews 1988, Burreson and Ragone Calvo 1996), simulated parasite abundance peaked approximately 2–3 months after annual maximums in temperature were observed. Under favorable salinity conditions parasite growth occurred at temperatures greater than 20°C, and parasite death occurred at temperatures less than 18°C. Hence, abundance increased from late spring until early fall and decreased from late fall to early spring.

The magnitude of parasite abundance maximums and minimums was modulated by salinity. *Perkinsus marinus* abundance progressively decreased with decreasing salinity. This pattern, which is the result of slower growth rates at low salinities compared to high salinities, is also observed in natural populations. *Perkinsus marinus* prevalence and infection intensity in oysters sampled along a salinity gradient in the upper James River, Virginia were correlated with salinity (Burreson and Ragone Calvo 1996). Summer and fall *P. marinus* infection intensities in oysters from the lower-most salinity areas were always light in intensity while moderate and heavy intensity infections were common in oysters collected from higher salinity areas (Burreson and Ragone Calvo 1996). Similarly, the abundance of overwintering parasites was higher in higher salinity areas than in lower salinity areas (Burreson and Ragone Calvo 1996).

Correlations between predicted parasite abundance and actual observed abundance were surprisingly strong, indicating that the main factors responsible for the regulation of *P. marinus–C. virginica* population dynamics in the upper James River, Virginia have been incorporated in the model. However, there remains room for improvement and some discussion regarding the deviation of predicted abundance from actual observed abundance. The strength of the correlation between the predicted and observed data decreased with decreasing salinity. This deviation may be in part due to two reasons. First, actual observed abundance data were calculated from a database that relied on a semi-quantitative diagnostic method. It is likely that some error was associated with the conversion of the semi-quantitative data to a quantitative format. The numerical ranks assigned (2, 4, and 6) to convert infection intensity scores (light, moderate, and heavy) to weighted prevalence were restrictive in setting lower and upper limits to the data. Much of the deviation observed in the DWS simulation is likely a result of this conversion. The model consistently generated lower minimum parasite abundance than that observed in the actual data; however, by assigning all infections that were categorized as light a ranking value of 2, the observed data minimums were most likely somewhat inflated. Second, there may be differences in parasite susceptibility between the three oyster populations. Wreck Shoal oysters, located farther down river, have likely experienced much stronger selection pressure from the parasite than Horsehead Rock and Deepwater Shoal oysters. That selection pressure may have affected parasite division and mortality rates, hence, parasite rates that were calibrated based on Wreck Shoal data may not be the best fit for the stations located farther upriver.

The results of sensitivity analysis indicated that several factors are important in determining model performance. The model was sensitive to salinity and temperature as well as to both parasite division and mortality rates. Interestingly, the degree of the model's sensitivity to these parameters varied with oyster bar. A twenty-percent change in the parameters had a lesser effect at Wreck Shoal than at Horsehead Rock and Deepwater Shoal. Since Horsehead Rock and Deepwater Shoal are located farther upriver than Wreck Shoal they more frequently experience salinity declines, which can be unfavorable for both parasite and host. It is likely that environmental thresholds affecting parasite and host activities are more frequently approached in the upriver locations. Estuarine environments experience large salinity and temperature fluctuations in relatively short time periods. In developing the model we derived our principal *P. marinus*-salinity relationships from a record of monthly field data that did not allow us to characterize the effect of shorter-term environmental fluctuations. Furthermore, it is likely that there are lag periods associated with initiation of parasite and host activities following the occurrence of a threshold condition. As presently constructed, lag times are not considered in the model. More detailed information about the environmental control of parasite division and mortality rates would improve model performance. This information would best be provided by experimental studies under controlled conditions.

Perhaps one of the most interesting results of the simulations was the fact that at WS and HH, a steady-state parasite abundance could be generated without the input of annual transmission events. Although parasite extinction ultimately occurred at DWS under conditions of no transmission, extinction took a period of nearly 6 years. These simulations suggest that a single transmission event may be sufficient for *P. marinus* to become enzootic within specific year classes of oysters in the moderate to high salinity areas, while periodic transmission events are required for the parasite to persist within specific year classes in low salinity areas. In the moderate–high salinity areas, parasite abundance would ultimately decrease as the pool of infected oysters is diluted by the presence of new recruits and the parasite would eventually become extinct when all infected hosts die. *Perkinsus marinus* became established in the upper James River oyster seed bed areas as a consequence of several consecutive drought years in the mid 1980s. Since that time the parasite has continued to be present in these historically disease-free areas. If the model simulations are correct, this would suggest that more than one transmission event has occurred in these low salinity areas. This clearly presents a very interesting area of focus for future research that could lead to the development of new management strategies. The current conceptual model of *P. marinus* transmission dynamics maintains that transmission occurs as infective cells are disseminated from dead hosts. Since there is little disease-associated mortality of oysters in

these low salinity areas, transmitted cells must be originating from live oysters or from downriver sources. Intensive harvesting of oysters from these downriver source areas, on a rotational basis, may be a means of preventing the recurrence of *P. marinus* transmission into the uppermost James River seed areas.

The outcomes of simulations generated by the model presented here are quite different from those presented by Powell et al. (1996). Powell et al (1996) developed a more complex model for *P. marinus* population dynamics coupled with oyster population dynamics in the Gulf of Mexico. Interestingly, their simulations were unable to generate an epizootic simply with changes in temperature and salinity. The outcomes of their simulations suggest that oyster populations must first be stressed by some other mechanisms before high temperature and high salinity conditions can facilitate epizootic oyster mortalities. They point to food availability and recruitment failure as two such mechanisms. Until the Chesapeake Bay model presented here is further developed to include host population dynamics the comparison with the Gulf of Mexico model remains problematic. However, it is interesting to note that results of simulations from both models indicate that once an epizootic is triggered it is very difficult to eliminate.

As currently constructed, this model provides realistic population simulations for *P. marinus* populations in the Chesapeake Bay. Development of the model has provided an excellent format for synthesizing data and for focusing attention on gaps in knowledge and research needs. Future development and evaluation of the model will yield a better assessment of thresholds for population maintenance and a better understanding of conditions that may lead to the termination of *P. marinus* epizootics and parasite extinction.

A BIOCHEMICALLY BASED MODEL OF THE GROWTH AND DEVELOPMENT OF *CRASSOSTREA GIGAS* LARVAE

ELEANOR A. BOCHENEK,[1] JOHN M. KLINCK,[2] ERIC N. POWELL,[1] AND EILEEN E. HOFMANN[2]

[1]Haskin Shellfish Research Laboratory, Rutgers University, 6959 Miller Ave., Port Norris, New Jersey 08349; [2]Center for Coastal Physical Oceanography, Crittenton Hall, Old Dominion University, Norfolk, Virginia 23529

ABSTRACT A biochemically based model was developed to simulate the growth, development and metamorphosis of larvae of the Pacific oyster, *Crassostrea gigas*. The model is unique in that (1) it defines larvae in terms of their protein, neutral lipid, polar lipid, carbohydrate, and ash content; (2) it tracks weight separately from length to follow larval condition index; and (3) it includes genetic variation in growth efficiency and egg quality to better simulate cohort population dynamics. The model includes parameterizations for larval filtration, ingestion, and respiration, which determine growth rate, and processes controlling larval mortality and metamorphosis. The initial biochemical content of the larva is determined by the composition of the egg. Changes in the initial ratios of protein, carbohydrate, neutral lipid, and polar lipid occur in response to the biochemical composition of available food as the larva grows. Modeling the process of metamorphosis requires a series of size-based and biochemically based triggers: (1) larvae become potentially competent to metamorphose at 275 μm, following a decrease in filtration rate at 250 μm; (2) larvae become competent to metamorphose when a daily decline in neutral lipid of 25% or more occurs; and (3) larvae metamorphose successfully if neutral lipid stores exceed polar lipid stores. Although based on simple biochemistry, the model succeeds in simulating such basic characteristics of *C. gigas* larval development and metamorphosis as larval life span and size structure at metamorphosis and the influence of egg and food quality and food quantity on survival. These results suggest that simple biochemical constructs may encompass the biochemical transitions most prominent in determining cohort success. Simulations of larval development show that for the smallest larvae, assimilation does not provide adequate resources to explain observed growth, although measured filtration rates would indicate otherwise. Egg lipid stores are needed to sustain the larva. The simulations also identify egg sizes in the range 37–73 μm to be viable, very similar to observations. Egg sizes outside this range are predicted to be nonviable due to lipid deficiencies in early larval life. Similarly, simulations identify upper and lower genetic limits on growth efficiency beyond which larvae cannot acquire sufficient neutral lipid stores to successfully metamorphose. As food supply declines, animals with high growth efficiencies are selected in the simulation. Low-protein food diets are predicted to increase larval survival. High-protein diets result in insufficient carbohydrate and neutral lipid to cover metabolic and storage needs. Thus, the influence of growth efficiency is nonrandomly distributed across egg size and respiration rate and the influence seems to be mediated in part by food quantity and to a larger measure by food quality.

KEY WORDS: *Crassostrea gigas*, larvae, Pacific oyster, growth, development model, biochemical, food

INTRODUCTION

For benthic species that have a planktonic larval phase of their life history, survivability of the larvae is the key determinant of recruitment to the adult population. Thus, much research has gone into identifying factors affecting the growth, development, metamorphosis, and settlement of larvae, especially for species with commercial value, such as the Pacific oyster, *Crassostrea gigas*.

Larvae of *C. gigas* undergo growth and development that is typical of bivalve larvae, with progression through D-shaped, umbo, and pediveliger stages (Fig. 1). The fraction of developmental time spent in each stage is variable and the rate at which the larvae progress through each is affected by local temperature, salinity, and food conditions (Helm & Millican 1977, Malouf & Breese 1977, Nascimento 1980, Gerdes 1983a, His & Maurer 1988, Nell & Holliday 1988; His et al. 1989, Pauley et al. 1988, Arakawa 1990, His & Seaman 1992, Robinson 1992, Thompson & Harrison 1992, Laing 1995, Thompson et al. 1996). The range of fractional development times reported for the small umbo to pediveliger stages (Fig. 1) is a reflection of these effects on larval growth.

Once spawned, the ultimate fate of *C. gigas* larvae is determined by the interaction of a number of factors. The first is the initial biochemical composition of the egg released by the adult, in particular the initial egg lipid content. Studies have shown correlations between egg size, lipid content, and bivalve larval development (Helm et al. 1973, Gallager et al. 1986, Gallager & Mann 1986a, Lee & Heffernan 1991). An implication of these studies is that initial egg lipid content is a determinant of larval survivorship and success at metamorphosis.

A second factor is the ability of the larvae to grow and develop so that total time spent in the plankton is minimized, thereby reducing exposure to mortality from predation. Because spawning pulses by adult populations, in nature, occur at widely variable times throughout the spawning season, larvae experience a widely varying set of environmental conditions. The timing of environmental conditions relative to a particular phase of larval life can greatly affect the total time needed for larvae to complete development (Dekshenieks et al. 1993). The concept of a critical period immediately post-hatch during which many planktonic larvae are particularly susceptible to low food supply is now well established (Cushing & Dickson 1976, Anger et al. 1981, Taggart & Leggett 1987), and the available data for bivalve larvae support the sensitivity of larvae to periods of low food supply (Gallager et al. 1986, His and Seaman 1992, Laing 1995). Studies also suggest that food quality, not just food quantity, is a critical issue (Thompson et al. 1994, 1996). Insufficient dietary lipid, for example, significantly limits larval growth and survival (Helm et al. 1973, Gallager et al. 1986).

A third factor affecting larval survival is the ability to acquire sufficient internal energy stores to successfully complete metamorphosis and set. Studies have shown that larvae can reach the size

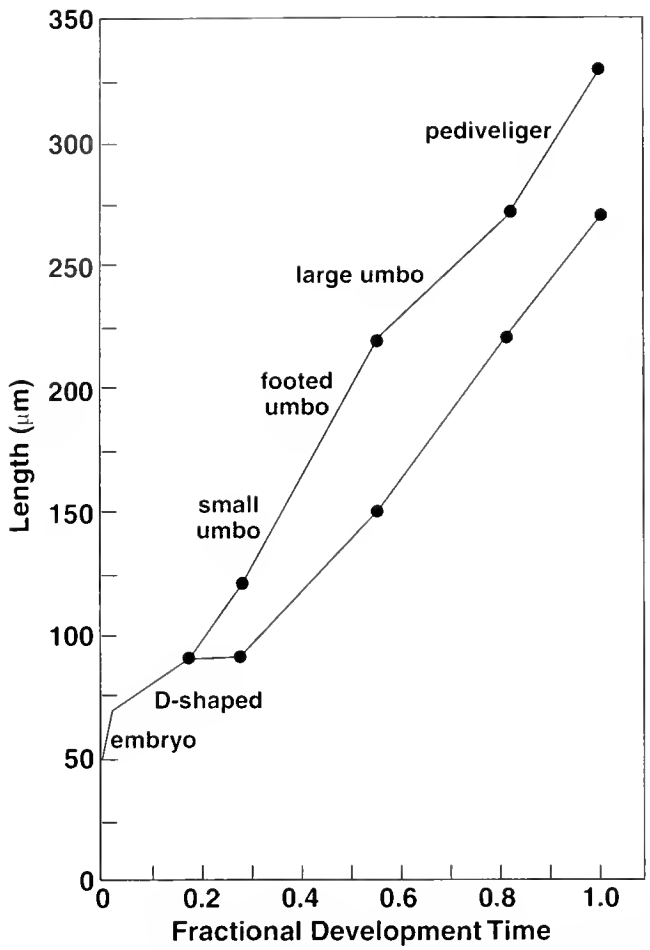

Figure 1. Schematic of the developmental stages of *Crassostrea gigas* larvae as a function of fraction of development time. The two curves bracket the range of sizes for the different stages, as reported in Arakawa (1990).

needed for metamorphosis but be unable to complete this step (Robinson 1992, Haws et al. 1993, Laing 1995). The possibility that a short-term deprivation of food early in larval life may reduce metamorphosis success can be inferred from a variety of studies that emphasize the critical importance of adequate food throughout larval life.

The increasing emphasis on the importance of an adequate diet, including quantity and quality, in determining a larval cohort's success and the recognition that adequate energy resources are needed for successful metamorphosis suggest the need to incorporate biochemical transfers into models of larval growth and development. The existing larval models determine growth from ingestion rate, decremented by the energy losses due to respiration and incomplete digestion (e.g., Carlotti & Sciandra 1989, Dekshenieks et al. 1993, 1996). These types of models, however, cannot be used to examine issues of food quality, nor can they be used to simulate the energy-reserve hypothesis underlying metamorphosis success. To investigate the influences of food quality and quantity on growth, development, and successful metamorphosis of *C. gigas* larvae, a biochemically based model was developed that includes explicit parameterizations for the metabolism of protein, carbohydrate, polar lipid, and neutral lipid within the standard parameterizations of energy flow via ingestion, assimilation, and respiration.

The following section provides a description of the *C. gigas* larval model and the parameterizations used in this model. This is followed by simulations that illustrate the effect of initial egg size, food quality, food quantity, and environmental conditions on larval growth, survival, and success at metamorphosis. The discussion section places these simulations within the context of the current understanding of the effect of environmental conditions and food quality on larval growth, survival, and metamorphosis.

MODEL DESCRIPTION

Model Structure and Governing Equation

The change in length for an individual larva over time is given by:

$$\frac{dL}{dt} = \alpha L \tag{1}$$

where L is larval length in μm and α is the rate at which the larva grows and has units of day^{-1}. Larval growth rate (α) is based on formulations that allow differential metabolism of the protein, carbohydrate, and lipid content of the food ingested by the larva. Thus, net production is expressed as the difference between assimilated ingestion (AI) and respiration (R):

$$NP_i = AI_i - R_i \tag{2}$$

where i represents the four basic biochemical components included in the model: protein, polar lipid, neutral lipid, and carbohydrate. An increase in larval length occurs when the sum of the four, $\sum_{n=1}^{4} NP_i$ is positive; when larval condition index is maximal for a given size; and when the restrictions imposed by certain biochemical ratios are simultaneously met. Thus, excess net production, ENP, is the basic quantity responsible for larval growth.

The specification of ENP, which determines α, is based on filtration, the metabolism of carbohydrates, polar lipids, neutral lipids, and proteins within the larva, and the conversion of the metabolized food into structural components of the larva versus the conversion into storage material. A basic assumption in this model is that the formation of structural components determines the increase in larval length. Material converted into storage components (i.e., neutral lipids) does not result in increased larval length. The conversions and parameterizations used to model these processes are described in the following sections.

The *C. gigas* larval model given by Eq. (1) was solved numerically using a third-order Adams-Bashforth scheme (Canuto et al. 1988) with a time step of 0.1 day.

Model Parameterizations

Observations from field and laboratory studies were used to derive the relationships that describe the processes affecting net production of *C. gigas* larvae. The basic units used in the model are grams, joules, and μm, and these are not necessarily always consistent with the units used for measurements. Thus, the first step in developing the larval model was to obtain conversions that allow the model calculations and output to be consistent with measurements and to be compared with observations. Also, many of the larval processes vary in amplitude or even form with larval size, requiring that relationships used to describe these be size dependent.

Length-to-Dry Tissue Weight Conversion

Numerous field and laboratory data sets exist that can be used to derive a length-to-dry tissue weight relationship for *C. gigas* larvae. However, the reporting of these data sets is quite variable, with some reported in terms of dry tissue weight (Gerdes 1983a) and others reported in terms of whole animal weight (His & Maurer 1988, Nascimento 1980, Waldock & Nascimento 1979). Dry tissue weight is the desired unit for deriving this relationship, so the data sets reported as whole animal weight were multiplied by a factor of 0.25, which corrects for the shell being 75% of the animal weight (His & Maurer 1988). The resultant data set (Fig. 2) was used to obtain the length-to-dry tissue weight relationship:

$$W = aL^b \tag{3}$$

where W is larval weight in ng and L is larval length in μm. The coefficients a and b are given in Table 1. The correspondence between Eq. (1) and the data sets is shown in Figure 2.

Length-to-Ash Weight Conversion

His and Maurer (1988) provide measurements of the percent of total dry weight as a function of larval size. These values were obtained by summing the percent organic matter represented by larval protein, carbohydrate, and lipids that were determined independently. As a comparison, His and Maurer (1988) also determine the percent total dry weight of organic matter by combustion of the whole animal. These data form the basis for developing a relationship to relate larval length to ash weight.

Comparison of the organic matter values determined by the sum of the components and those obtained from the heating method differ by about 5%. The difference was assumed to be due to protein, which is more completely measured by the heating method, so this difference was added to the protein value for a given size larva. The percent total dry weight for the largest larval size measured by His and Maurer (1988), 274 μm, was reduced from 29.1% to 26.2% because attempts at using the higher value to produce a relationship between larval length and ash weight gave unrealistic results. The reduction in percent total dry weight was obtained by maintaining the same proportional difference in the heating and sum of component determinations of percent dry weight as reported for other larval sizes. The rationale for the reduction in value is that the measured value included effects of metamorphosis that are not explicitly included in the larval model. The percent total dry weight for the 274 μm larva was also applied to the measured dry weight (7000 ng) for 320 μm larvae to provide an additional data point at the larger size.

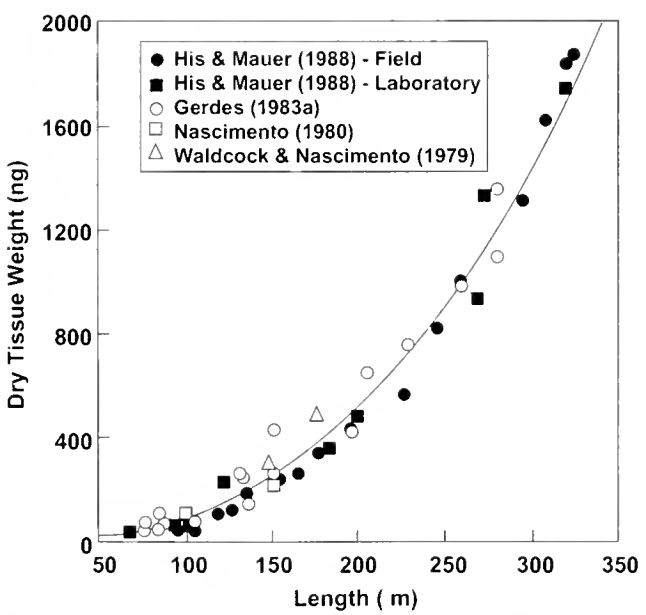

Figure 2. Dry tissue weight as a function of *Crassostrea gigas* larval length.

TABLE 1.

Definition, units, and values for the variables used in the *Crassostrea gigas* larva model equations.

Variable	Definition	Units	Value
a	constant	ng	6.745×10^{-4}
b	constant	none	2.557
c	constant	ng larva^{-1}	3.931×10^{-3}
d	constant	none	2.440
a_1	constant	none	0.3436
a_2	constant	μm^{-1}	−0.00347
a_3	constant	μm^{-2}	2.0323×10^{-5}
a_4	constant	μm^{-3}	-3.1107×10^{-8}
FR_o	constant	1 day^{-1}	24×10^{-6}
b_1	constant	none	−2.0909
b_2	constant	μm^{-1}	0.0335
b_3	constant	μm^{-2}	-3.2798×10^{-5}
c_1	constant	none	96.9948
c_2	constant	μm^{-1}	−1.1011
c_3	constant	μm^{-2}	4.3×10^{-3}
c_4	constant	μm^{-3}	-5.5985×10^{-6}
γ	constant	none	0.0025
α	constant	none	0.35
β	constant	none	0.08
L_o	initial larva length	μm	calculated
L_f	larva length	μm	100
δ	constant	none	0.5
L_s	larva length	μm	0.5
λ	maximum neutral lipid usage	% day^{-1}	75.
SL	upper larval size for neutral lipid use	μm	80.
r_o	base respiration rate	KJ day^{-1}	calculated
θ	constant	none	0.96
m_o	daily mortality rate	day^{-1}	
ES_o	central egg size	μm	50
$Resp_o$	central respiration rate	KJ day^{-1}	1.046
$2sd_{egg}$	standard deviation, egg size	μm	0.2
$2sd_{resp}$	standard deviation, respiration rate	KJ day^{-1}	0.2

The length-to-ash weight data set was fit with a regression of the form

$$AW = cL^d \tag{4}$$

where AW is larval ash weight in ng larva^{-1} and the coefficients c and d are given in Table 1. The correspondence between the data and fitted curve is shown in Figure 3.

Length-to-Protein-to-Ash Ratio Conversion

The protein values for the different sized larva reported in His and Maurer (1988) were divided by the corresponding larval ash

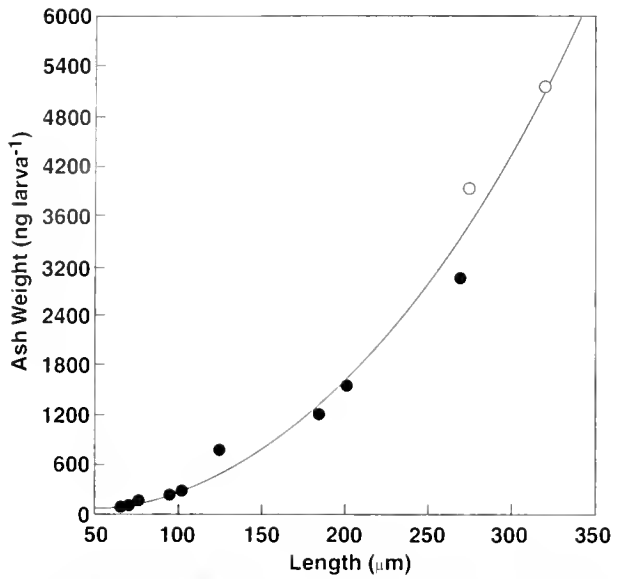

Figure 3. Ash weight as a function of *Crassostrea gigas* larval length. The solid circles are measurements given in His and Maurer (1988). The open circles represent measurements given in His and Maurer (1988) that were modified as described in the text.

weight values, determined as described in the previous section, to obtain protein-to-ash ratios as a function of larval size (Fig. 4). The curve fit to these data is of the form:

$$PAR = a_1 + a_2 L + a_3 L^2 + a_4 L^3 \quad (5)$$

where *PAR* is the protein-to-ash ratio and the coefficient values are given in Table 1. This relationship describes a ratio that decreases from a value of 0.27 to a minimum of 0.18 at a larval size of about 100 μm, after which it again increases. The initial decrease is associated with the development of shell. The increase in the ratio as the larva gets larger reflects the decrease in the surface-to-volume ratio of the larva as it grows.

Carbohydrate, Protein, Polar Lipid, and Neutral Lipid Conversions

In the model, conversions between carbohydrate, lipid, and protein were needed to account for the debiting of the biochemical pools to cover the metabolic cost of respiration and the movement of carbon between different tissue types. The needed conversions are of two types. Those for respiratory demands are expressed in terms of energy (e.g., joules); those for tissue conversions are expressed in terms of moles carbon.

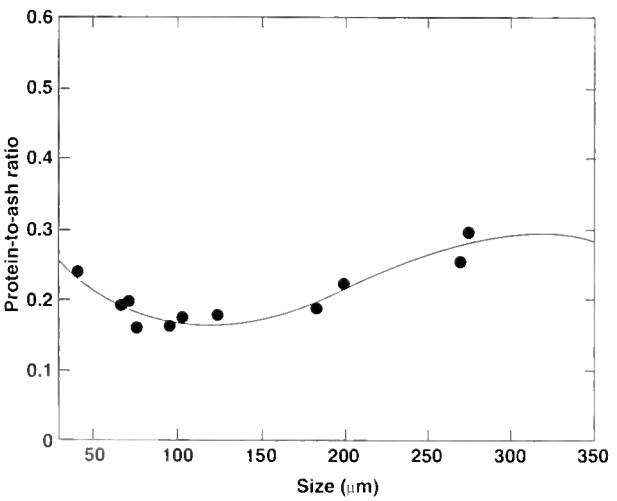

Figure 4. Protein-to-ash ratio as a function of *Crassostrea gigas* larval length. The solid circles are the ratios calculated from the protein and ash values given in His and Maurer (1988).

Respiratory demands were converted to equivalent energy values using 39.5 kJ g^{-1} for lipids, 23.6 kJ g^{-1} for protein, and 17.2 kJ g^{-1} for carbohydrates. These conversions are based on data given in Mann and Gallager (1985), Trytek and Allen (1980), and Crisp (1971).

Interconversion of biochemical constituents was based on carbon equivalent weights using palmitic acid, serine, and glucose residues, respectively, to define the ratio between moles carbon and molecular weight. In this way, carbon atoms were conserved, but the total constituent weight changed depending upon the contribution of carbon to the molar weight. So, for example, the conversion of tissue carbohydrate to tissue lipid is based on a ratio of 1.929, which expresses the relative weight of lipid and carbohydrate based on the equivalency of carbon atoms.

In addition, certain weight ratios between structural constituents were associated with healthy larvae. When in sufficient quantity, assimilated food constituents were allocated to tissue pools using these ratios. Deviations in the resulting tissue composition from these ratios resulted in mortality. The relationship between tissue lipid and protein was obtained from His and Maurer (1988), under the assumption that the total lipid content of *C. gigas* larvae, like *C. virginica* larvae, is about evenly split between neutral and polar lipids (Gallager et al. 1986, Whyte et al. 1987). This yielded a preferred tissue polar lipid-to-tissue protein ratio of 0.11 for healthy larvae. Information from the same sources was used to establish the equivalent ratio between tissue carbohydrate, most of which was assumed to be structural since neutral lipid is the primary storage constituent, and tissue protein. The value of the tissue carbohydrate-to-tissue protein ratio was set at 0.01. Both ratios were independent of larval size.

Parameterization of Processes

Filtration Rate and Filtration Efficiency

Filtration is the basic process by which *C. gigas* larvae obtain food. Therefore, accurate representation of this process is needed for larval growth to be correctly simulated. Gerdes (1983a) presents measurements of filtration rates for *C. gigas* at a range of food concentrations and larval sizes. These data show three distinct phases of larval filtration (see Fig. 8 in Gerdes 1983a). Initial filtration rates are low until the larva reaches about 100 μm, after which filtration rate increases exponentially to its maximum as the larva reaches 250 μm. At this size, larval behavior changes as the larva nears metamorphosis and filtration rate decreases dramatically.

The filtration rate observations given in Gerdes (1983a) were used to derive empirical relationships that provide the basic filtration structure of the model (Fig. 5):

$$FR = FR_o e^{(b_1 + b_2 L + b_3 L^2)}, \quad \text{for larva} \leq 250\ \mu\text{m} \quad (6)$$

$$FR = FR_o e^{(c_1 + c_2 L + c_3 L^2 + c_4 L^3)}, \quad \text{for larva} \geq 250\ \mu\text{m} \quad (7)$$

where *FR* is filtration rate. The coefficients in Eqs. 6 and 7 are given in Table 1.

Initial simulations that used the above relationships for larval

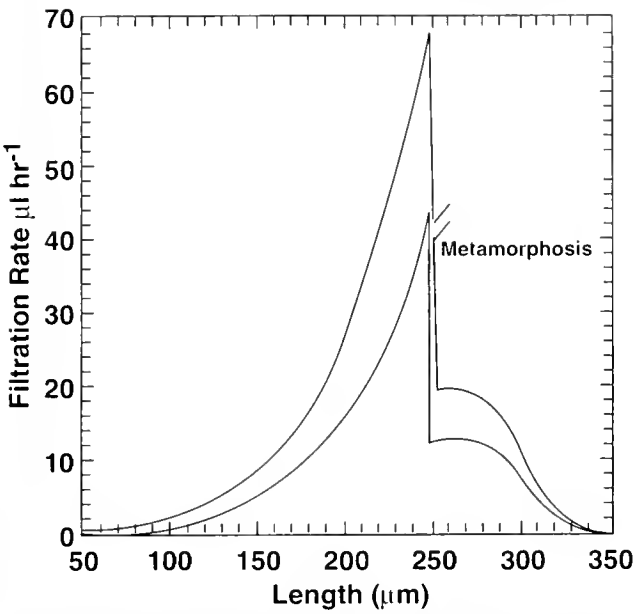

Figure 5. Upper curve, filtration rate as a function of *Crassostrea gigas* larval length calculated from Eqs. 6 and 7 as described in the text. Lower curve: filtration rate after corrections described by Eqs. 8 and 9 (for food concentration of 2 mg L^{-1}).

filtration rate resulted in growth rates that were too high. Reduction of the growth rate was accomplished by adding a factor to the filtration rate that reduces ingestion efficiency. This factor is of the form:

$$IE = \frac{\gamma}{Food}\left[\alpha + \beta\left(\frac{L - L_o}{L_f}\right)\right] \qquad (8)$$

where ingestion efficiency (IE) is a nondimensional quantity that depends on the ambient food concentration ($Food$) and larval size. Coefficient values are given in Table 1. The relationship given by Eq. 8 results in reduced feeding efficiency for all larval sizes, but with the maximum reduction associated with smaller larvae.

The rationale for reducing filtration efficiency is that the vellum is a multipurpose organ, so there must be some inefficiency in each of the activities and functions of this organ; otherwise the larvae could only swim at the rate that allows maximum ingestion and dispersal, and escape capabilities would be compromised. Thus, filtration rates measured in a laboratory setting for *C. gigas* larvae should be regarded as measures of vellum activity and not as measures of ingestion. In addition, most research has been conducted using saturating food concentrations. This would exacerbate any tendency for more food to be filtered from the water column than could be ingested by the larva.

Applying the ingestion efficiency factor (Eq. 8) to Eqs. 6 and 7 resulted in realistic larval growth rates, except for larvae smaller than 80 µm. Early in larval life the rapid changes leading to the development of the organs for feeding and digestion should further limit ingestion and/or assimilation efficiency. Thus, the filtration rate for small larvae (FR_s) was further reduced by:

$$IE_s = IE \cdot \delta \cdot \left(1 + min\left(1., \left(\frac{L - L_o}{L_s - L_o}\right)\right)\right) \qquad (9)$$

The above approach is based on the assumption that the vellum in small larvae is very inefficient at capturing food particles and/or that digestion is less efficient in small larvae. Coefficient values and definitions are given in Table 1.

A relationship between low food supply and increased feeding efficiency due to enlargement of the vellum (Strathmann et al. 1993) was not included in the model because the influence of vellum enlargement on filtration rate is unknown. The model may underestimate growth rate at low food supply.

Temperature and Salinity Effects

As with most bivalve larvae, the metabolic processes controlling growth in *C. gigas* larvae are affected by temperature and salinity (Lee & Lee 1968, Helm & Millican 1977, Ventilla 1984). His et al. (1989) provide measurements of larval growth rate for salinities between 20‰ and 35‰ and temperatures between 15°C and 30°C. These measurements start with larvae with a mean shell length of 57 µm, which is prior to the development of the D-shaped stage (Fig. 1), and extend through the first seven days of larval growth. The differences in the measured larval growth, for the fed larvae, between day 0 and day 7 were calculated for each temperature and salinity. The resultant values were linearly interpolated to obtain growth rates at intermediate temperature and salinity values. Normalizing this matrix of growth rates to the growth rate at 25°C and 30‰ provides the fractional change in larval growth rate at a given temperature and salinity (Fig. 6).

The measured growth rates given in His et al. (1989) were extended to the entire range of temperature encountered by *C. gigas* larvae by assuming that larval growth rate decreases in a linear fashion to zero between 15°C and 0°C and to zero between 30°C and 35°C. This pattern in growth rate is based on observations of increased larval abnormalities in these temperature ranges (Arakawa 1990). Similarly, for salinity, the growth rate at 20‰ was linearly reduced to zero at 10‰, after which growth rate remained zero. This was based on observations of increased larval abnormalities at low salinities (Arakawa 1990). For salinities above 35‰, larval growth rate at 40‰ was assumed to be one-half

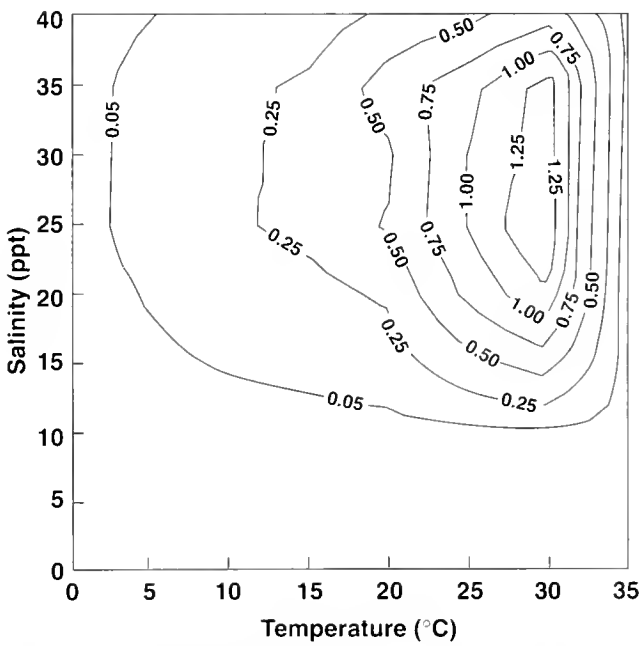

Figure 6. Fractional change in *Crassostrea gigas* larval growth rate as a function of temperature and salinity.

the larval growth rate at 35‰, and growth rates at intermediate salinities were obtained by linear interpolation. The assumption of reduced growth rate at 40‰ is based on measurements (Nell & Holiday 1988) that show *C. gigas* growth rate at 39‰ being one-half the value at 35‰.

The fractional change in larval growth over the entire range of temperature and salinity was verified by comparing simulated larval length with reported larval lengths measured at known temperatures and salinities (Helm & Millican 1977, Nell & Holiday 1988, His et al. 1989, Robinson 1992). These comparisons showed excellent agreement between simulated and observed larval length, except for lengths between 150 and 200 μm. At these sizes, mismatches of 10 to 45 μm occurred for the higher temperature and salinity values. Larvae of this size are growing rapidly at salinities above 24‰ and temperatures above 25° C, and hence the growth curves are steep. Therefore, slight mismatches in the reporting of measured length for a given larval age can greatly affect comparisons with simulated lengths.

Food Composition and Assimilation Efficiency

The *C. gigas* larval model allows for differential metabolism of protein, carbohydrate, polar lipid, and neutral lipid. For this to occur, the food ingested by the larva must be expressed in terms of the relative contribution of each of these biochemical constituents. Based upon measurements reported in Utting (1986), Roman (1983), and Lee et al. (1971), the average biochemical composition of marine algae, in terms of ash-free dry weight, was taken to be 3 parts protein, 2.5 parts carbohydrate, 0.6 parts polar lipid, and 0.4 parts neutral lipid. This basic structure defines the food reservoir for the larvae, for most simulations.

Handa (1969) provides assimilation efficiencies for plant material of 1.0 for protein, 1.0 for polar and neutral lipids, and 0.2 for carbohydrates. The reduced assimilation efficiency for carbohydrates arises because 80% of plant carbohydrate is structural or β-linked carbohydrate (e.g., the refractory portion) that cannot be digested by animals and is therefore not available as food. The available 20% represents labile carbohydrate. Multiplication of these assimilation efficiencies with the corresponding food fraction gives an overall assimilation efficiency for *C. gigas* larvae of about 0.7, which is within the range expected for bivalve larvae (estimated from growth efficiency by Jorgensen 1952).

Initial simulations showed that the above assimilation efficiencies resulted in growth rates for larvae less than 80 μm, which were too small. Observations show a drawdown of neutral lipid reserves during early larval life in *C. gigas* and *C. virginica* (Gallager et al. 1986, Gallager and Mann 1986a, Whyte et al. 1987, His & Maurer 1988), presumably to fill the carbon needs not covered by feeding. In the model, the early life stages of the larva were allowed to use neutral lipid stores to form structural material in the body. This was done by calculating a small larva factor (SLF_i) of the form:

$$SLF_i = max\left[0., \lambda\, \Delta t \left(\frac{SL - L}{SL - L_o}\right)\right] \qquad (10)$$

where i indicates protein, carbohydrate, polar lipid, or neutral lipid. This relationship calculates the proportionate length change for larva smaller than 80 μm in a given time increment (Δt), and the neutral lipid reserves are then used in proportion to the carbon requirement needed to sustain the change in length. The maximum neutral lipid that is used, given by λ, occurs when larvae are at their initial size, L_o. This amount decreases proportionately as the larva grows and becomes increasingly capable of feeding, and is zero at 80 μm. The mobilized neutral lipid is then converted into equivalent protein, carbohydrate, and polar lipid using the biochemical conversions given previously. This is the only instance in the model where protein is created *de novo*, rather than being obtained from food.

Thus, the assimilated ingestion (AE_i) can be expressed as the product of the filtration rate (FR), the ingestion efficiency (IE_s), temperature and salinity effects ($TSfactor$), food ($Food_i$), the assimilation efficiency (AE_i), and the small larvae factor (SLF_i) as:

$$AI_i = FR \cdot IE_s \cdot TSfactor \cdot Food_i \cdot AE_i \cdot SLF_i \qquad (11)$$

Fate of Assimilated Ingestion

The assimilated ingestion obtained from Eq. (11) is parameterized in terms of protein, neutral lipid, polar lipid, and carbohydrate, and the fate of each of these biochemical constituents differs within the larva (Table 2). Protein assimilated in a given time interval has, as its primary destination, the somatic protein pool. Protein may also be used to cover a respiratory deficit (discussed below) in accordance with the appropriate protein-to-carbohydrate-to-polar lipid ratio.

The carbohydrate needs of the larva are determined by the amount needed to maintain tissue carbohydrate in its proper proportion and that needed to cover the metabolic process of respira-

TABLE 2.

Destination of assimilated protein, carbohydrate, polar lipid, and neutral lipid in *Crassostrea gigas* larvae.

Food constituent	Primary destination in larva	Food deficit response	Food surplus response	Tissue maintenance deficit	Early life (<80 μm)
Protein	somatic P	NA	NA	respiration (P:C:PL)	NA
Carbohydrate	somatic C & respiration (P:C)	somatic PL (P:PL)	neutral lipid reserve	respiration (P:C:PL)	NA
Polar lipid	somatic PL (P:PL)	somatic C (P:C)	neutral lipid reserve	respiration (P:C:PL)	NA
Neutral lipid	neutral lipid reserves	somatic C (P:C); somatic PL (P:PL) respiration	NA	somatic C (P:C); somatic PL (P:PL); respiration	somatic C; somatic PL; somatic P; respiration

The particular biochemical ratio determining the conversion to individual reservoirs is indicated. Table columns two, three, and four indicate the fate of the food; column five indicates the fate of the tissue. Transfers of food that do not occur in response to deficit or surplus conditions are indicated by NA. Protein, carbohydrate, and polar lipid are indicated by P, C, PL, respectively.

tion (Table 2). Assimilated carbohydrate is the primary means by which larval respiratory needs are met (Table 2). The required somatic carbohydrate is determined so as to maintain the carbohydrate-to-protein ratio (0.01), and this amount is debited from the available assimilated carbohydrate and added to the carbohydrate pool. Excess carbohydrate (food surplus response in Table 2) becomes part of the larval neutral lipid reserve. When tissue imbalances occur (e.g., insufficient polar lipid to meet the tissue compositional requirements of the larvae), somatic carbohydrate is used to maintain larval polar lipid in its proper proportion.

The primary destination of assimilated polar lipid in the larva is the somatic polar lipid pool in accordance with the protein-to-polar lipid ratio (Table 2). Excess assimilated polar lipid goes to the larval neutral lipid pool. When carbohydrate imbalances occur, polar lipid reserves are mobilized to produce somatic carbohydrate in an amount that is consistent with maintaining the protein-to-carbohydrate ratio. Polar lipids are also used to cover tissue maintenance deficits arising from respiratory demands.

The primary destination of assimilated neutral lipid is the neutral lipid pool (Table 2). This internal pool is mobilized to maintain somatic carbohydrate and somatic polar lipid pools in accordance with the appropriate ratios when assimilated protein, carbohydrate, and polar lipid are not present in the proper proportions in the food. The neutral lipid pool can also be used to cover respiratory needs during periods of carbohydrate deficit. This pool also provides a means for small larvae, less than 80 μm, to produce somatic carbohydrate, polar lipid, and protein as well as cover respiratory costs early in larval life.

At any point in the development of the larva, the inability to maintain one of the biochemical constituent ratios or the inability to remove a deficit in a biochemical pool results in death of the larva.

Respiration

Respiration provides the only metabolic loss of assimilated energy in the *C. gigas* model. Measurements show that respiration rate for *C. gigas* larvae increases with larval size and with temperature (Fig. 7). Laboratory measurements of respiration rate for *C. gigas* larvae cover a range of larval sizes measured at 25°C (Gerdes 1983b) and 20°C (Hoegh-Guldberg & Manahan 1995) can be described by the relationship:

$$Resp = r_o W^n \tag{12}$$

where *Resp* is given in mL O_2 consumed ind^{-1} h^{-1} and W is animal dry tissue weight in mg. The base respiration rate, r_o, is assumed to reflect genetic variations in metabolic processes that are known to occur for individual *C. gigas* larvae (e.g., Lannan 1980). Hence, this parameter is specified using a distribution (described in a following section) that is assumed to represent metabolic variability within the larval population. Other coefficients are defined in Table 1. The respiration rates measured at 25°C (Fig. 7) were used along with the fractional changes in growth rate (Fig. 6) to obtain the full range of temperature and salinity effects on larval respiration. Respiration rate was converted to an energy demand using 20.21 J (mL O_2 consumed)$^{-1}$ to determine the metabolic cost of respiration.

Equation (12) provides the metabolic cost of respiration that must be met by the larva. As discussed in the previous section, the assimilated carbohydrate pool provides the first biochemical reservoir that is used to meet this demand (Table 2). This pool is converted to equivalent energy units using the conversions given previously, and the needed carbohydrate is removed from the pool. Any excess is added to the neutral lipid pool in an amount that is consistent with the carbohydrate-to-lipid ratio (Table 2).

If the assimilated carbon pool is insufficient to meet the cost of respiration, then the remaining deficit is taken from the neutral lipid pool and any remaining deficit is then taken proportionately from the structural components of the larva (Table 2). Periods during which the larva resorts to using structural material to cover metabolic costs result in reduction of larval condition index defined in the model as a reduction in the protein-to-ash ratio.

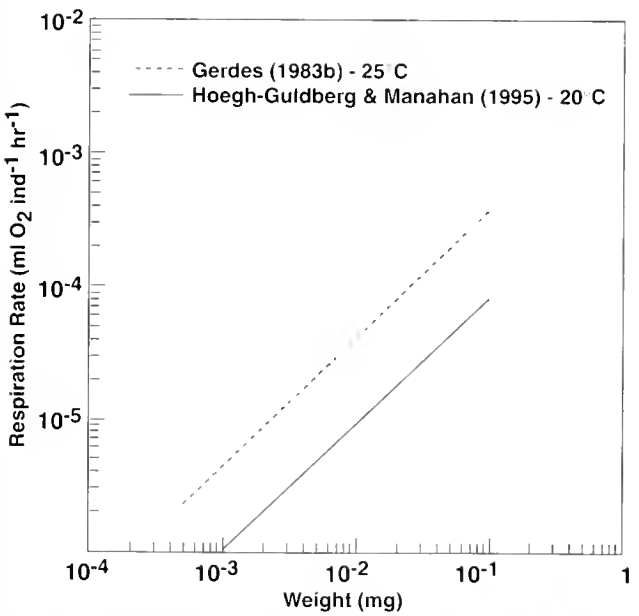

Figure 7. ***Crassostrea gigas*** **larval respiration rate measured as a function of larval weight at two temperatures.**

Larval Growth

Larval growth in a given time interval is based on maintaining the protein-to-ash ratio (Fig. 4, Eq. 5) for a given larval length. Larval growth resulting in an increase in length is assumed to occur when the protein, carbohydrate, and polar lipid pools are in excess of what is needed to maintain the protein-to-ash ratio at a given size. This is the excess net production (*ENP*) that determines α in Eq. 1.

Excess protein is obtained by subtracting from the protein pool the amount that is needed to maintain the ash weight at a given larval length, as is determined by the protein-to-ash ratio. The excess polar lipid and carbohydrate pools are computed from the excess protein pool based on the required structural ratios of these constituents. The excess net production for a given time interval is the sum of the excess protein, polar lipid, and carbohydrate. This gives the excess net production in a given time interval in terms of an increment in larval weight. The weight increment is then used with the length-to-dry tissue weight relationship (Fig. 2) to obtain an incremental increase in length for the increase in weight.

During times of protein deficit with respect to ash weight (low condition index), the larva can have a positive net production that increases organic mass and condition index, but produces no excess net production and, hence, no increase in length.

Larval Metamorphosis

Observations suggest that once *C. gigas* larvae reach 275 μm they may initiate metamorphosis and this process may or may not be successful (Ventilla 1984, Kusaki 1991, Laing 1995). Thus, in the model, the larva is assumed to have the potential of becoming competent for metamorphosis at 275 μm. Just prior to this point, at a length of 250 μm, filtration rate declines. Observations show that *C. gigas* larvae can become competent for metamorphosis over a range of sizes. This implies that the switch between Eqs. 6 and 7 controlling the point where filtration rate changes might contain a size dependency, determined by some metabolic process that is, as yet, unknown. Not having this information, the point at which the larva can become competent for metamorphosis was fixed at a size a little larger than the size observed by Gerdes (1983a) for the change in filtration rate. Simulations discussed subsequently support this decision.

Once the larva reaches 275 μm, it becomes competent to metamorphose if it experiences a 25% drop in neutral lipid stores in one day. This is determined by the interrelationship of food supply, filtration rate, and respiration rate. Competency is triggered by a decrease in neutral lipid that, if continued, would impair successful metamorphosis. Once competent, the larva immediately attempts metamorphosis. Successful completion of metamorphosis occurs if the larval neutral lipid pool is greater than the polar lipid pool. This establishes a minimum storage requirement needed to sustain metamorphosis. If this condition is not satisfied, then metamorphosis is unsuccessful and the larva dies.

Biochemically Determined Metabolic Mortality

The simulated larval growth prior to metamorphosis is based on maintaining specific ratios between protein, polar lipid, carbohydrate, and ash weight. Small variations in these ratios are allowed, consistent with changes that occur in the larva as it grows (cf. Fig. 4). However, large changes are not permissible. The interdependencies of the biochemical ratios results in the protein-to-ash ratio being a good indicator of the biochemical state of the larva. If this ratio is reduced at any time to 70% or less of its needed value, then larval condition index is too low and the larva is assumed to die. This condition is termed starvation in the model.

During the initial stages of larval growth, about the first two days, the larva does not filter efficiently (Fig. 5), and hence food ingestion is not usually sufficient to cover metabolic costs. During this period, it is assumed that the larva survives by using its stored neutral lipid supply. However, if during this period the neutral lipid supply approaches zero, the larva is assumed to have reached its metabolic point of no return and dies. Also, inability of the larva to maintain its required protein-to-lipid and protein-to-carbohydrate ratios results in death.

Model Implementation

Initial *C. gigas* Egg Size, Including Genetic Variability

The eggs spawned by *C. gigas* adults have an average size of 50 μm (Quayle 1988, Arakawa 1990). However, using this as the initial condition for the model resulted in mismatches in the initial simulated and observed length-to-weight relationships, which are based on larval size. Thus, simple egg diameter is not the appropriate metric for use with the length-to-weight and other conversions. The discrepancy arises because of the mismatch in volume of a spherical egg and the more ellipsoidal-shaped larva. Therefore, it was necessary to convert initial egg diameter to an equivalent larval size. This was done using a diameter-to-length conversion factor of 1.096 (Arakawa 1990) that conserves volume in going from a spherical egg to an ellipsoidal-shaped larva. Thus, a 50 μm egg is equivalent to a 54.8 μm larva.

C. virginica egg size is observed to range between 30 and 80 μm (Gallager et al. 1986). More limited information is available for *C. gigas*, but a similar range of egg sizes can be inferred (Breese & Malouf 1975). This variation was assumed to represent genetically or environmentally determined variability in the spawning population. Therefore, for each simulation, the initial conditions included a range of egg sizes.

To establish the initial biochemical composition of the egg, the larval size immediately post-hatch was used with the length-to-dry tissue weight relationship (Fig. 2) to calculate an initial dry weight, which in turn was used to obtain an initial ash weight value (Fig. 3). The protein component of the egg was then determined by multiplying the ash weight by the protein-to-ash ratio. The egg polar lipid content was determined by multiplying the protein content by the polar lipid-to-protein ratio. The carbohydrate content was taken to be 1% of the dry weight of the modified egg. Egg neutral lipid content was obtained by difference through subtracting the protein, polar lipid, and carbohydrate weight from the initial dry weight value. If this calculation resulted in a negative value of neutral lipid, which can occur for very small eggs, the egg was assumed to be nonviable.

Predation and Other Nonmetabolic Sources of Larval Mortality

The larval model provides, as output variables, the total time for larval development, larval size at the end of the simulation, and a description of why the simulation ended. Termination of a simulation occurs because of successful metamorphosis, unsuccessful metamorphosis, inappropriate metabolic ratios, and starvation. The simulated larval results are then examined with a submodel that calculates larval survivorship based on the timing of mortality and the larval life span of the survivors for each combination of egg size and respiration rate represented by the genetic variability assigned to the cohort. Losses to nonmetabolic sources of mortality, such as predation, are evaluated at this point with losses increasing in proportion to the larval life span obtained for each combination of egg size and respiration rate. The resultant simulated distributions of survivorship can then be compared with similar values reported from field and laboratory studies.

Predation and other forms of nonmetabolic mortality (*EM*) are imposed during the larval period using a relationship assumed to be of the form

$$EM(j,k) = e^{-m_{\nu}LD(j,k)} \tag{13}$$

where the daily mortality rate, m_{ν}, is the same as that used for *C. virginica* larvae (Dekshenieks et al. 1997) and *LD* is the total time required for a larva with an initial egg size (j) and respiration rate (k) to trigger a mortality event or to successfully metamorphose. The longer the larva takes to develop, the higher the chance of nonmetabolic mortality.

Genetic Effects on Larval Mortality

Growth, mortality, and other population processes are apportioned based on genetic variability, in which certain combinations of initial egg size and respiration rate are less common in the cohort and in which certain combinations are less viable overall,

either due to metabolic imbalances, metabolic inefficiencies, or longer larval life spans increasing nonmetabolic mortality. This type of genetically determined outcome, *GE*, is prescribed with a Gaussian function of the form:

$$GE = e^{-\left(\frac{ES - ES_o}{2sd_{ES}}\right)^2} - e^{-\left(\frac{Resp - Resp_o}{2sd_{Resp}}\right)^2} \quad (14)$$

where the Gaussian distributions extend for two standard deviations ($2sd_{egg}$, $2sd_{Resp}$) about a central egg size and respiration rate that are given by ES_o and $Resp_o$, respectively. Coefficient definitions and values are given in Table 1. Equation 14 weights mortality or any other population process by a population distribution that is characterized by a certain range of egg sizes and respiration rates. Thus, the surviving larval population represents the combined effects of genetics, food composition, and environmental conditions.

RESULTS

Reference Simulation

The reference simulation was run with near-optimal environmental conditions of 25°C, 30‰, a food concentration of 2 mg L^{-1}, and food with a protein, polar lipid, neutral lipid, carbohydrate ratio of 3:0.6:0.4:2.5. Development of *C. gigas* larvae over the first few days of larval life is primarily sustained by egg neutral lipid stores. The drawdown of neural lipid stores results in a decrease in the neutral lipid-to-protein ratio (Fig. 8A). The decrease in this ratio is most pronounced for eggs with small initial sizes. For initial egg sizes of 40 to 50 μm, the neutral lipid-to-protein ratio approaches zero. All larvae, independent of initial egg size, reach a maximum ratio value of between 0.15 and 0.165 and a size of ≥275 μm (Fig. 8B). Larvae arising from larger eggs reach these values earlier, and hence can metamorphose earlier. Once a size of 250 μm is reached, filtration rate declines and so, too, does the neutral lipid to protein ratio. However, growth continues and most larvae metamorphose at about 300 μm, regardless of initial egg size (Fig. 8B).

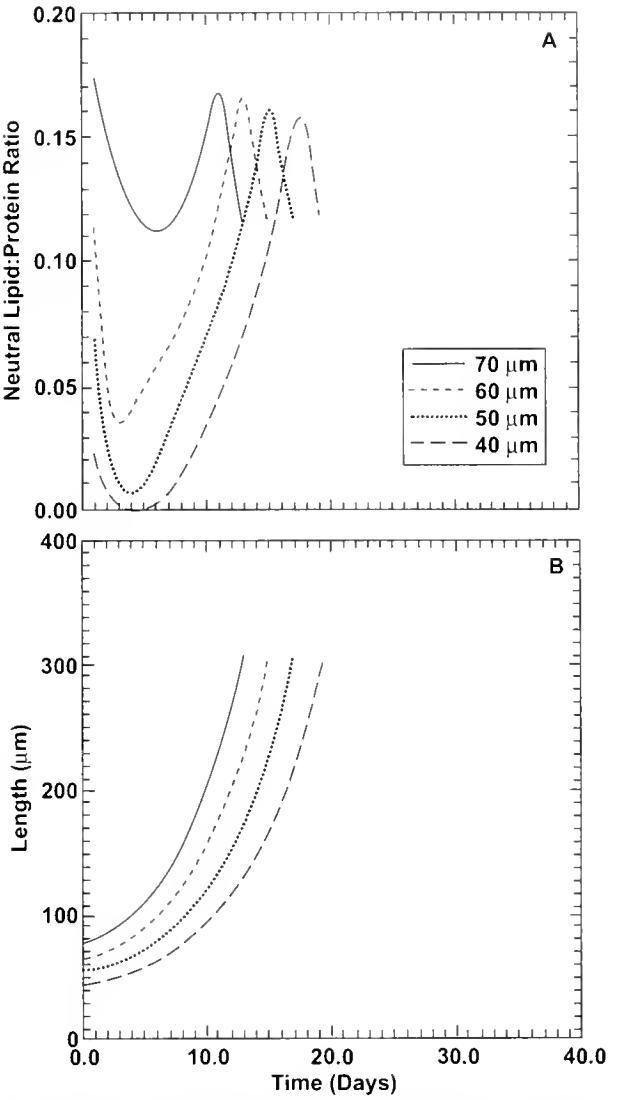

Figure 8. Simulated time development of the (A) neutral lipid-to-protein ratio and (B) *Crassostrea gigas* length obtained for a selection of initial egg sizes from 40 μm to 70 μm.

The simulated larval growth is exponential and independent of initial egg size (Fig. 8B). Larvae reach 100 μm, which corresponds to the small umbo stage (cf. Fig. 1), in 4 to 12 days for initial egg sizes of 70 μm and 40 μm, respectively. The rate of growth accelerates after 100 μm. The time required for the larvae to reach 300 μm ranges from 13 to 19 days for the largest and smallest initial egg sizes, respectively. The development time required for the 50 μm egg to reach 300 μm is 17 days, which agrees with development rates measured at 25°C and 30‰ (His et al. 1989). The range of simulated development times is also consistent with those reported for *C. gigas* larvae (Quayle 1988, Arakawa 1990, Laing 1995).

The effect of variations in initial egg size and growth efficiency on the fate of the larvae is summarized by the state of the larva at the time it either dies or successfully completes metamorphosis (Fig. 9). Variations in growth efficiency are modeled as variations in respiration rate; however, similar results would be obtained if the variation was in any component of Eq. 2. Initial egg sizes less than 37 μm result in nonviable larvae for all respiration rates. Initial egg sizes above 73 μm result in eggs that do not have sufficient neutral lipid stores after day 2 to continue development at all respiration rates. The large initial size of these eggs results in an imbalance in neutral lipids that cannot be corrected subsequently (cf. Fig. 8A). A similar fate occurs for initial egg sizes between 40 and 50 μm that yield larvae with high base respiration rates. For these larvae, too much of the neutral lipid pool is required to cover respiratory demand, and this produces a metabolic imbalance from which the larva cannot recover. Above and below the region of initial egg sizes and base respiration rates that produce successful metamorphosis are regions where the larva develops to the point of attempting metamorphosis, but is unable to do so successfully. A drop in neutral lipid triggers metamorphosis in these larvae, but they have insufficient lipid stores to cover the metabolic costs of metamorphosis.

At the population level, the fraction of the larvae that survive to complete metamorphosis is dependent on the initial egg size (Fig. 10A), with the distribution of survivorship centered around an initial egg weight of 50 μm, which is the center of the egg size distribution. Survivorship tapers off toward larger egg sizes, with essentially no survival to metamorphosis at egg sizes greater than 68 μm. Survivorship at smaller egg sizes decreases abruptly with essentially no survival at sizes less than 40 μm. Larval survivorship as a function of base respiration rate (Fig. 10B) is maximal at

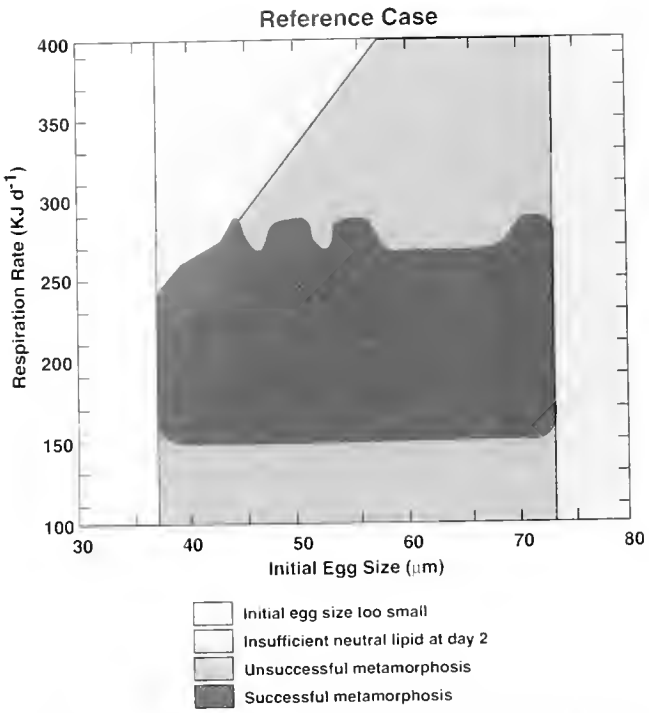

Figure 9. Simulated time development of *Crassostrea gigas* larvae for a range of initial egg sizes and base respiration rates. The simulation used the reference case environmental conditions of 25 C, 30‰, and a food concentration of 2 mg L^{-1} with a protein, polar lipid, neutral lipid, and carbohydrate ratio of 3:0.6:0.4:2.5, respectively.

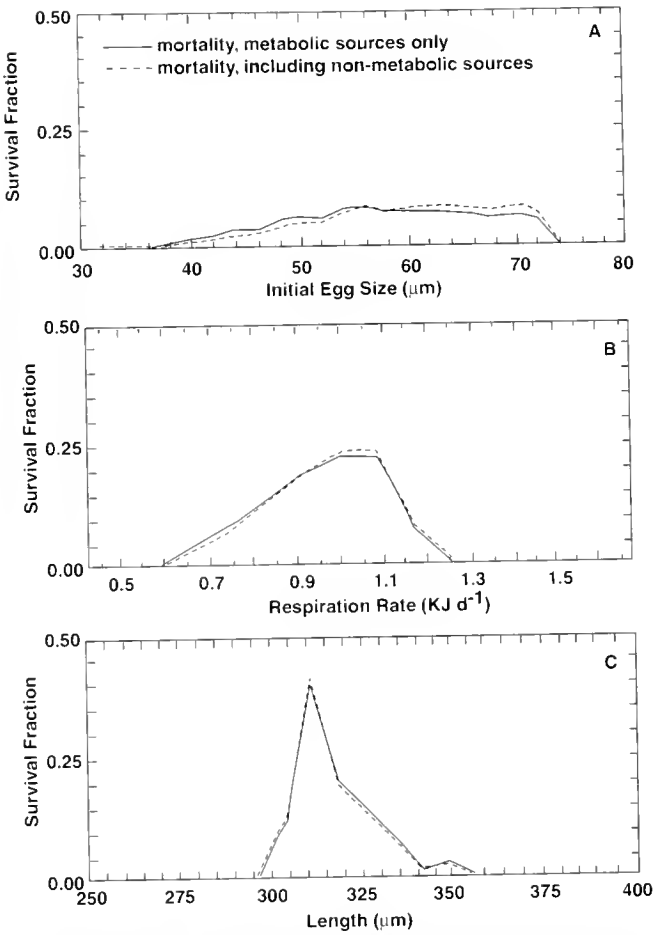

Figure 10. Simulated *Crassostrea gigas* larval survival as a function of (A) initial egg size, (B) base respiration rate, and (C) larval length at metamorphosis, using the reference case environmental conditions given in Figure 9.

rates around 1.05 KJ day^{-1}. Respiration rates above this result in an abrupt decrease in survival, with no survival at rates above 1.254 KJ day^{-1}. Larval survival at respiration rates below 1.05 KJ day^{-1} slowly decreases and is zero at rates below 0.628 KJ day^{-1}. Most larvae reach sizes between 300 and 325 µm before metamorphosis (Fig. 10C).

Detailed verification of the reference simulation is difficult because data on larval biochemical composition, as it varies with egg size, development time, and environmental conditions, are meager. General trends in larval success as measured by survivorship, larval size, and larval life span are much better known. Four such trends are observed in the simulation. (1) Adequate neutral lipid stores are a prerequisite of high survival during the critical period a few days post-hatch and at metamorphosis. The reference simulation demonstrates both effects (Figs. 8A, 10B). (2) Typically, egg size ranges from 40–60 µm. The reference simulation identifies this range as optimal for *C. gigas*, based on changes in biochemical composition dictated by larval energetics (Fig. 10A). (3) Successful metamorphosis occurs for larvae of 295–340 µm in the reference simulation. This is a frequently observed size range (Ventilla 1984, Kusaki 1991, Laing 1995). (4) Larval life span for the most successful egg sizes varies from about 14 to 17 days, a range that approximates the norm in observation (Ventilla 1984, Arakawa 1990, Laing 1995).

Effect of Larval Filtration

The parameterization for larval filtration (Eqs. 6 and 7, Fig. 5) is based on the assumption that the filtration response changes abruptly at 250 µm. *C. gigas* larvae are observed to metamorphose at a range of lengths. The change in filtration rate is an important contributor to the mechanisms by which the model determines the onset and success of metamorphosis. Therefore, the larval length at which the change in filtration response occurs was varied.

Varying the onset of a decline in filtration rate does not impact the range of viable egg sizes because this range is determined by events that predate this point in the larva's life span (Figs. 11A, 11B). However, if filtration rate changes at 270 µm, larvae spend a longer time at a high filtration rate. These animals metamorphose successfully over a wider range of base respiration rates than those that support successful metamorphosis when filtration rate begins to decline at 250 µm (Fig. 12B). Also, the overall population survivorship is higher; 78.8% of the cohort versus 62.4% in the reference simulation (Figs. 9, 10), and the range of lengths at which larvae metamorphose is wider (Fig. 12C).

Moving the larval length at which the filtration rate response changes to a smaller size, 230 µm, results in a limited range of base respiration rates at which successful metamorphosis can occur (Figs. 11B, 13B). Many of the animals survive to attempt metamorphosis, but are unsuccessful at completing the process. The smaller size at which the filtration rate is reduced results in the larvae not storing enough neutral lipid to cover the metabolic needs associated with metamorphosis. Larval length at metamorphosis (Fig. 13C) is now limited to a small range of sizes.

Total population survivorship drops from 62.4% in the refer-

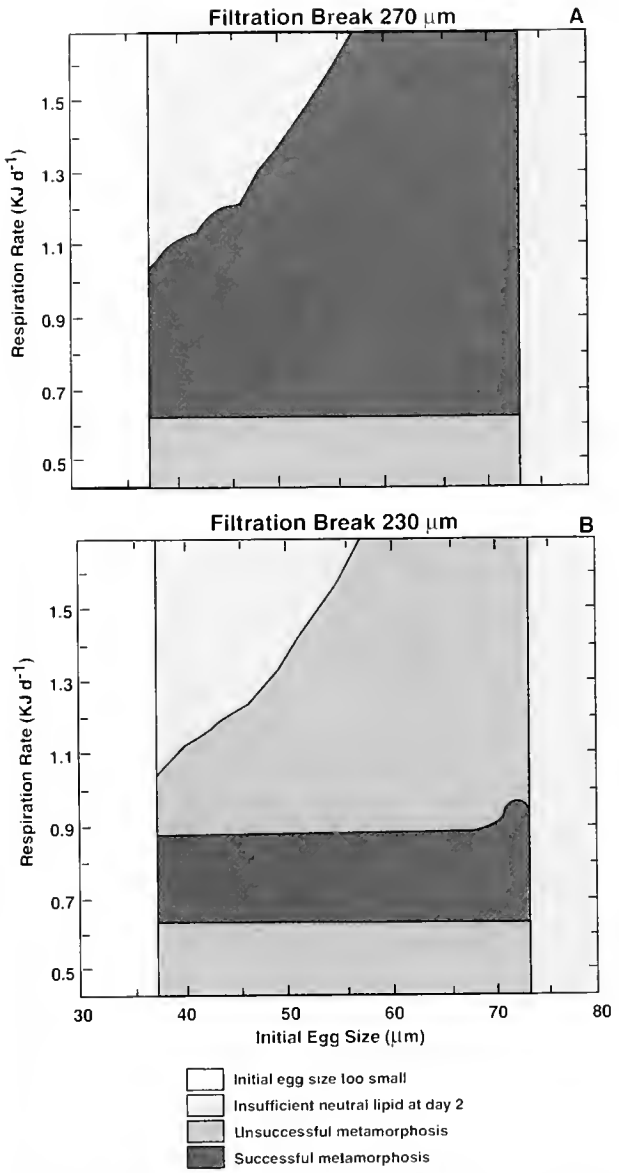

Figure 11. Simulated fate of *Crassostrea gigas* larvae for a range of initial egg sizes and base respiration rates in which the change in larval filtration rate response is at (A) 270 µm and (B) 230 µm. The simulation used the reference case environmental conditions given in Figure 9.

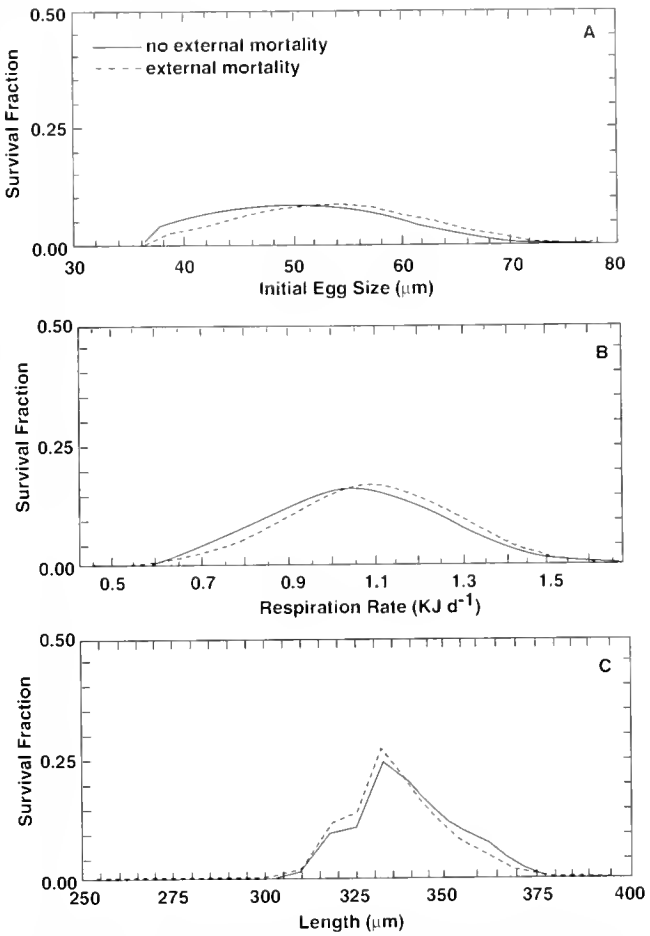

Figure 12. Simulated *Crassostrea gigas* larval survival as a function of (A) initial egg size, (B) base respiration rate, and (C) larval length at metamorphosis obtained when the change in larval filtration rate response occurs at 270 µm. The simulation used the reference case environmental conditions given in Figure 9.

ence case to 8.1% with a size trigger of 210 µm rather than 250 µm. Cohort survivorship declines dramatically at trigger sizes below 250 µm (Table 3) and asymptotes rapidly above 250 µm. At trigger sizes above 250 µm, some larvae do not metamorphose until reaching sizes much larger than normally observed (e.g., 375–400 µm, Fig. 12C), however. Accordingly, larval growth, as modeled, requires a filtration rate trigger near 250 µm to obtain observed levels of cohort survivorship and size at metamorphosis. This approximates the size where filtration rate declines are observed to take place (Gerdes 1983a).

Effect of Diet

Information on the effects of diet on growth and survival of *C. gigas* larvae indicate that high-lipid and low-protein diets are usually efficacious (Utting 1986, Thompson & Harrison 1992, Thompson et al. 1994, 1996). These trends are reproduced by the model.

A larval diet that is lacking in neutral lipid but contains the correct ratios of protein, polar lipid, and carbohydrate (3:0.6:0:2.5) results in animals that are unable to successfully complete metamorphosis at all ranges of initial egg size and base respiration rate (Fig. 14). Lack of neutral lipids results in more of the protein and carbohydrate pools being used to cover the demands of respiration and growth and, so, lipid stores are insufficient to sustain metamorphosis. In addition, the range of egg sizes and base respiration rates in which the neutral lipid store at day 2 is insufficient for further development is greatly expanded relative to what is obtained for a diet containing neutral lipid (Fig. 14 versus Fig. 9).

A diet in which the protein content is 50% higher relative to the standard diet (4:0.6:0.4:2.5) produces a similar result in that no combination of initial egg size or respiration rate results in successful metamorphosis (Fig. 15A). Larvae either have insufficient neutral lipid reserves at day 2 to continue development or attempt metamorphosis but fail to complete the process. A high-protein diet requires that more of the neutral lipid stores be used to cover tissue structural needs, and hence less lipid is stored for later use in metamorphosis.

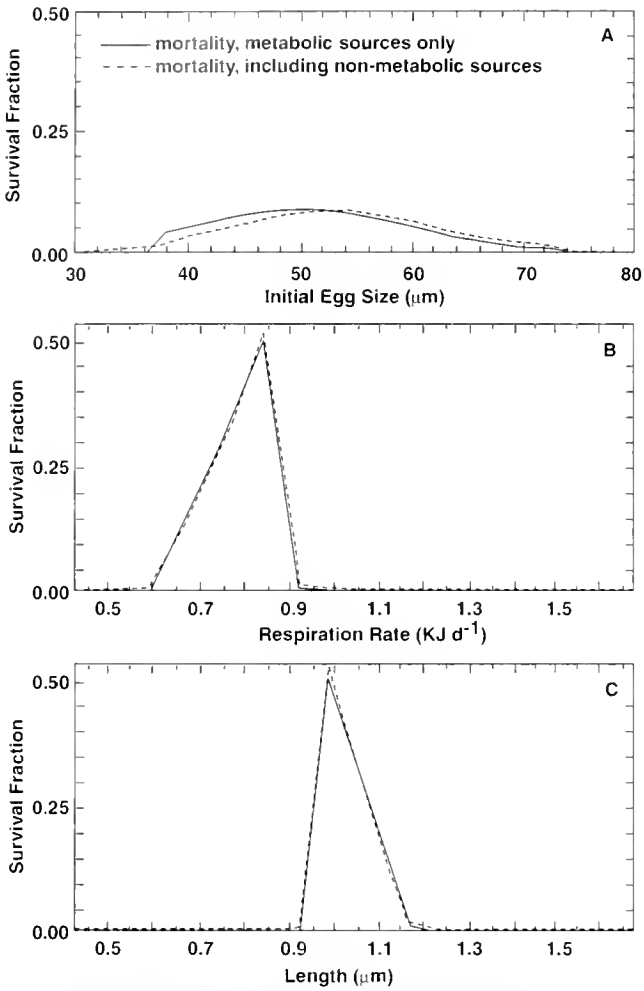

Figure 13. Simulated *Crassostrea gigas* larval survival as a function of (A) initial egg size, (B) base respiration rate, and (C) larval length at metamorphosis obtained when the change in larval filtration rate response occurs at 230 μm. The simulation used the reference case environmental conditions given in Figure 9.

A diet low in protein (2:0.6:0.4:2.5) is beneficial to the larva (Fig. 15B). Ingestion of low-protein food extends the range of respiration rates that result in successful metamorphosis (Fig. 15B versus Fig. 9). More polar lipid and carbohydrate is available to cover metabolic costs and to increase neutral lipid stores. This increases metamorphosis success. Simulations indicate that a low-protein diet increases overall population survivorship under hatchery conditions where nonmetabolic causes of mortality are minimized (88.8% from 62.4% in the reference simulation), but decreases survivorship under field conditions, from 6.1% in the reference simulation to 4.7%, due to slower growth and longer planktonic times increasing losses to predation.

TABLE 3.

Total population survivorship for simulated cohorts of *Crassostrea gigas* larvae in which the larval size triggering a change in filtration rate was varied from 210 μm to 290 μm.

Trigger size	210	230	250	270	290
Cohort survivorship	8.1%	17.2%	62.4%	78.8%	78.8%

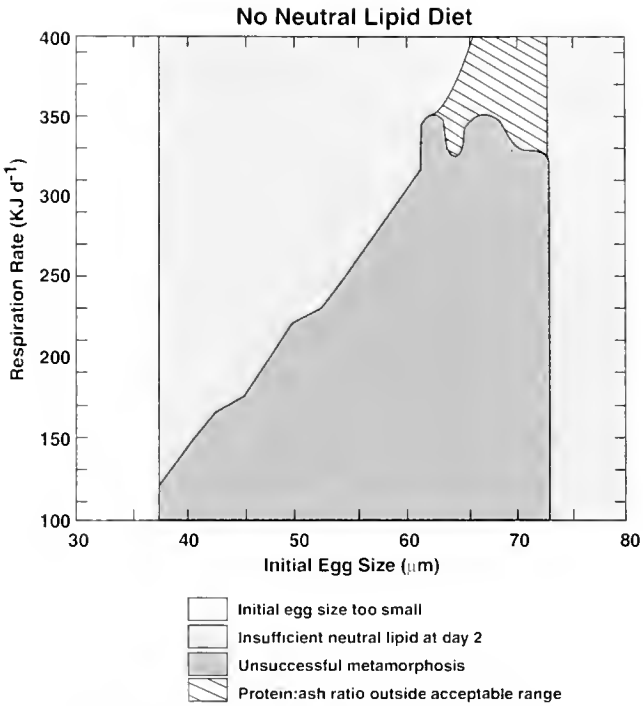

Figure 14. Simulated fate of *Crassostrea gigas* larvae for a range of initial egg sizes and respiration rates resulting when the larval diet includes no neutral lipid. The simulation used the reference case environmental conditions given in Figure 9, except that the food had a protein, polar lipid, neutral lipid, and carbohydrate ratio of 3:0.6:0:2.5.

Effect on Metamorphosis

The cue that is assumed to initiate metamorphosis is a 25% drop in the neutral lipid reserves of the larva over a span of one day. This level of decline was chosen as a metamorphosis trigger by comparing the simulated size and biochemical composition of metamorphosing larvae to measured values. The condition and size of larvae at metamorphosis is quite variable, and the metamorphosis trigger value used in the model represents one that simulates the average of these conditions.

Requiring only a 10% drop in neutral lipids in one day to trigger metamorphosis results in essentially all combinations of initial egg size and base respiration rate producing larvae that successfully undergo metamorphosis (Fig. 16 versus Fig. 9). The lower trigger value allows larvae to have a greater energy store at the time metamorphosis is attempted, and hence the probability of success is increased. At the population level, a wide range of egg sizes and base respiration rates results in survival (Figs. 17A & 17B), but larval length at metamorphosis is shifted to smaller larvae (Fig. 17C). The population mode in this case extends from 285 μm to about 305 μm, a size range predominately comprising sizes smaller than typically observed and smaller than the 295 μm to about 335 μm size range observed in the reference simulation (Fig. 9C). Increasing the trigger to a 40% reduction in neutral lipids in one day (not shown) results in attempted, but failed, metamorphosis at all initial egg sizes and base respiration rates. Thus, the value of 25% produces observed success rates for metamorphosis at a range of observed egg sizes not achieved by higher or lower trigger values.

Metamorphosis success is determined by the ratio of neutral

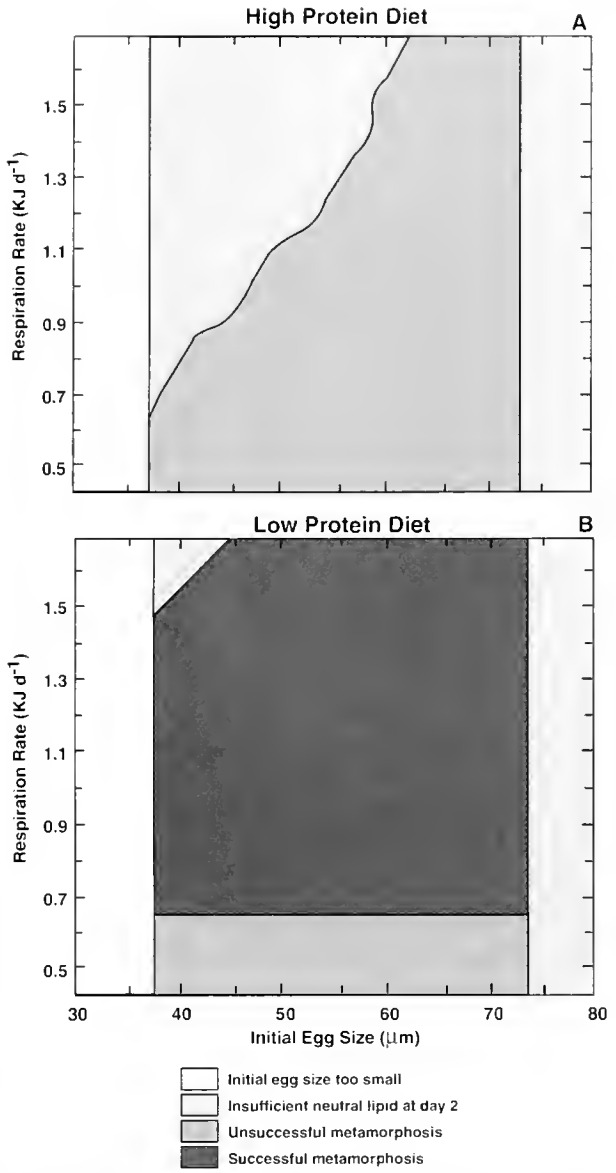

Figure 15. Simulated fate of *Crassostrea gigas* larvae for a range of initial egg sizes and respiration rates resulting when the larval diet is (A) high in protein and (B) low in protein. The simulation used the reference case environmental conditions given in Figure 9, except that the food had a protein, polar lipid, neutral lipid, and carbohydrate ratios of 4:0.6:0.4:2.5 and 2.5:0.6:0.4:2.5.

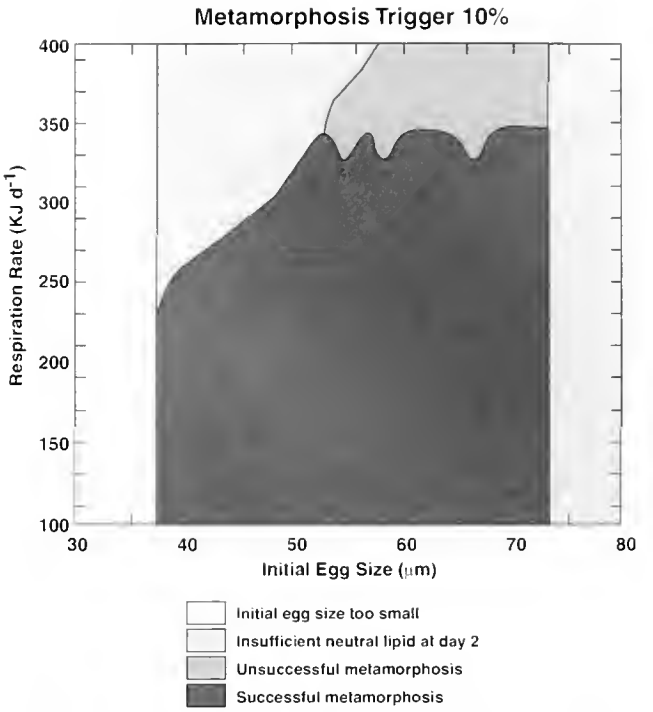

Figure 16. Simulated fate of *Crassostrea gigas* larvae for a range of initial egg sizes and base respiration rates when the trigger for metamorphosis is set to be a 10% drop in neutral lipid stores in one day. The simulation used the reference case environmental conditions given in Figure 9.

lipid to polar lipid in the animal at the time that metamorphosis is triggered. In the reference case (Fig. 9), successful metamorphosis occurs if the content of neutral lipid exceeds the content of polar lipid. Allowing metamorphosis to be successful when the larval neutral lipid reserves are greater than 80% of the polar lipid content produces successful metamorphosis over a large range of initial egg sizes and respiration rates (Fig. 18A). At the population level, larval survival is enhanced over a wide range of initial egg sizes and base respiration rates (Fig. 19A, 19B). The length at metamorphosis also extends over a wide range (Fig. 19C), wider than normally observed, but the mode of the population is still around 308 µm, as seen in the reference simulation (cf. Fig. 10C).

If metamorphosis is successful only when the neutral lipid pool is greater than 110% of the polar lipid pool, the range of initial egg sizes and respiration rates at which successful metamorphosis occurs is greatly reduced (Fig. 18B). The effect of egg size on larval survivorship is only somewhat modified (Fig. 20A); however, the range of base respiration rates that result in successful metamorphosis is greatly reduced (Fig. 20B), as is the range of larval lengths (Fig. 20C). Overall, trigger values above 100%, a 1:1 neutral lipid-to-polar lipid ratio, generate rates of successful metamorphosis that are too low and larval sizes at metamorphosis that are too large (Table 4). Trigger values below 100% at first seem to be defensible; however, survivorships are unusually high. Hence, model conditions chosen for the reference simulation include, as the minimally required neutral lipid stores for success at metamorphosis, a quantity greater than the polar lipid content of the larva (>1:1). Recall that the polar lipid content is constrained to a predetermined ratio with protein and structural carbohydrate, and so the same results would have occurred had neutral lipid been compared to any structural constituent.

Temperature and Salinity Effects

The temperature and salinity used for the previous simulations, 25° C and 30‰, is near optimal for the growth and development of *C. gigas* larvae (cf. Fig. 6). The optimal range of these environmental variables is narrow, and therefore relatively small changes in these conditions have the potential of causing large changes in larval growth and development. Population survivorship is nonzero over a relatively narrow temperature range and a somewhat wider salinity range (Table 5). A 5°C reduction in temperature, from 25°C to 20°C for example, results in no combination of initial egg size or base respiration rate that produces successful metamorphosis (Fig. 21A). A reduction in salinity to 20‰ extends the

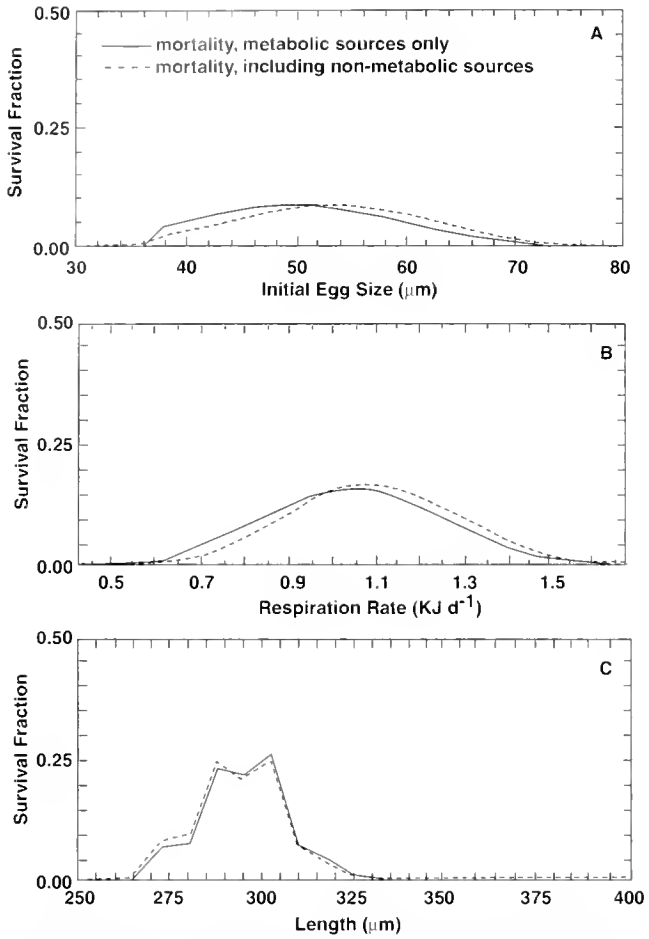

Figure 17. Simulated *Crassostrea gigas* larval survival as a function of (A) initial egg size, (B) respiration rate, and (C) larval length at metamorphosis obtained when metamorphosis occurs in response to a 10% drop in neutral lipid stores in one day. The simulation used the reference case environmental conditions given in Figure 9.

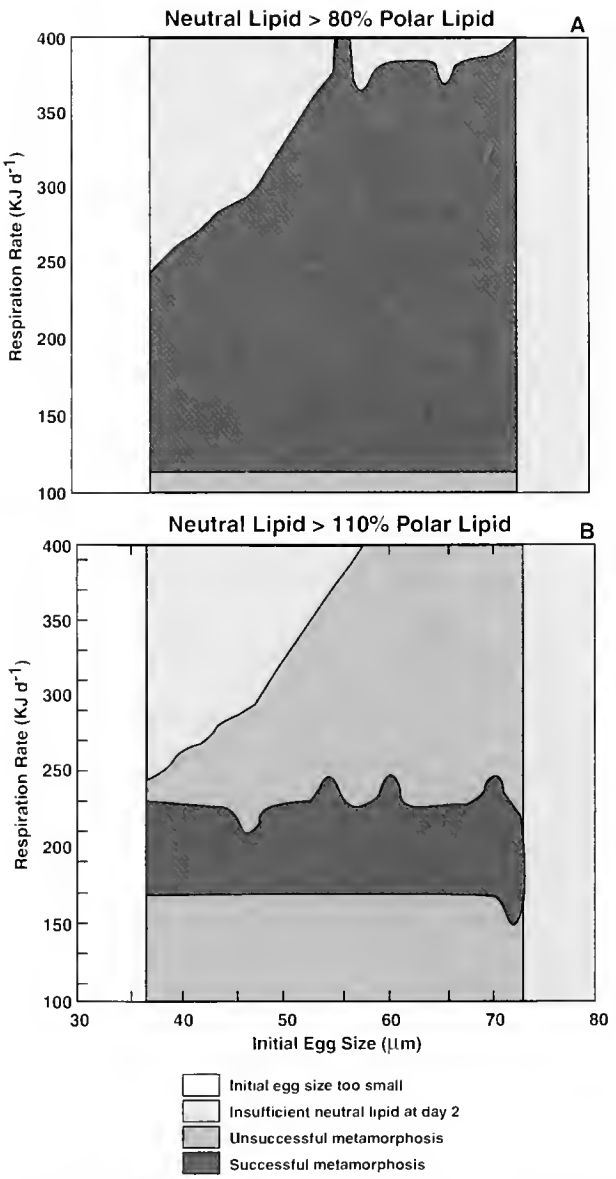

Figure 18. Simulated fate of *Crassostrea gigas* larvae for a range of initial egg sizes and respiration rates when the metamorphosis trigger occurs when (A) neutral lipids are greater than 80% of the polar lipid stores and (B) neutral lipids are greater than 110% of the polar lipid stores. The simulation used the reference case environmental conditions given in Figure 9.

range of initial egg weights and base respiration rates at which the larva exceeds its neutral lipid constraint at day 2 of development (Fig. 21B). Half as many animals exposed to this salinity successfully complete metamorphosis as in the reference case.

Effect of Variations in Food Resources

Environmental food concentration can vary over a wide range. Food concentration in excess of 2 mg L^{-1} used for the reference simulation (cf. Fig. 9) only extends somewhat the range of initial egg weights and base respiration rates that result in successful metamorphosis because 2 mg L^{-1} food is a saturating food concentration. However, a 50% reduction in food concentration, from 2 mg L^{-1} to 1 mg L^{-1}, significantly narrows the range of base respiration rates that result in successful metamorphosis (Fig. 22A). The strong coupling between respiration rate and food availability is not surprising since respiration is the primary metabolic loss that the larva must cover through ingestion. This result is further substantiated when looking at population level survival trends (Table 6). Survivorship declines rapidly at food concentrations below 2 mg L^{-1} and reaches zero at food concentrations of about 0.5 mg L^{-1}.

Certain environmental conditions may spare a decrease in food supply by permitting an increase in filtration rate. Increasing temperature in the previous simulation to 30°C, for example, increases survival by permitting some larvae with high respiratory demands to survive (Fig. 22B). Total population survival increases from 27.2% to 37.6% at the higher temperature.

Planktonic values of food of 0.5 mg L^{-1} or less are not unusual. Consequently, larvae may experience times of starvation due to significantly reduced food concentrations. A simulation in which food is available at a concentration of 2 mg L^{-1} for days 1 to 4 of larval development and unavailable after day 5 shows that no combination of initial egg size and base respiration rate results in successful metamorphosis (Fig. 23A). Death results from poor condition in some cases, but more frequently from metabolic imbalances between principal biochemical constituents. Simulated

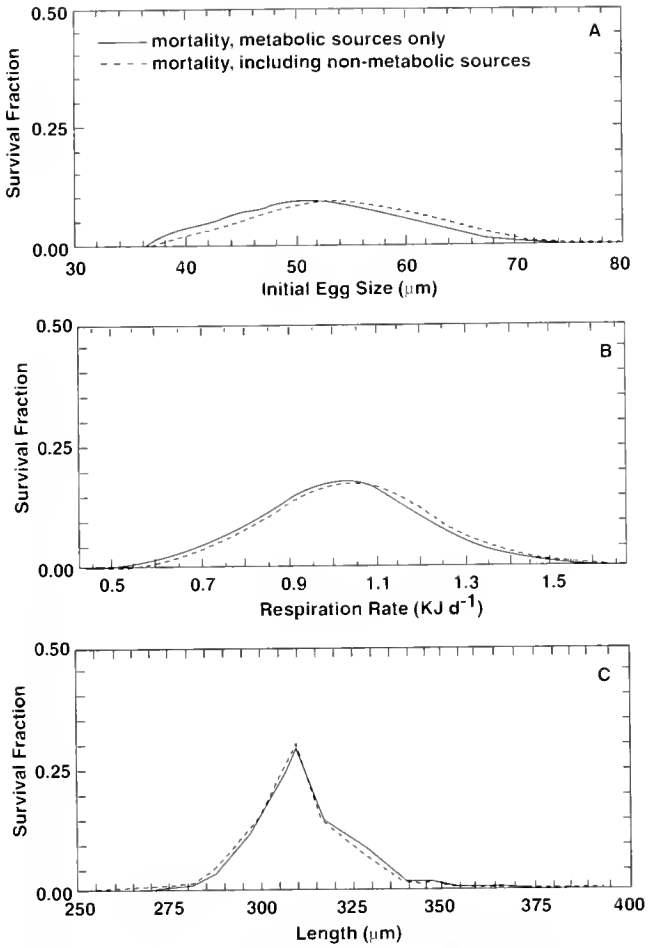

Figure 19. Simulated *Crassostrea gigas* larval survival as a function of (A) initial egg size, (B) base respiration rate, and (C) larval length at metamorphosis obtained when metamorphosis occurs when neutral lipids are greater than 80% of polar lipid. The simulation used the reference case environmental conditions given in Figure 9.

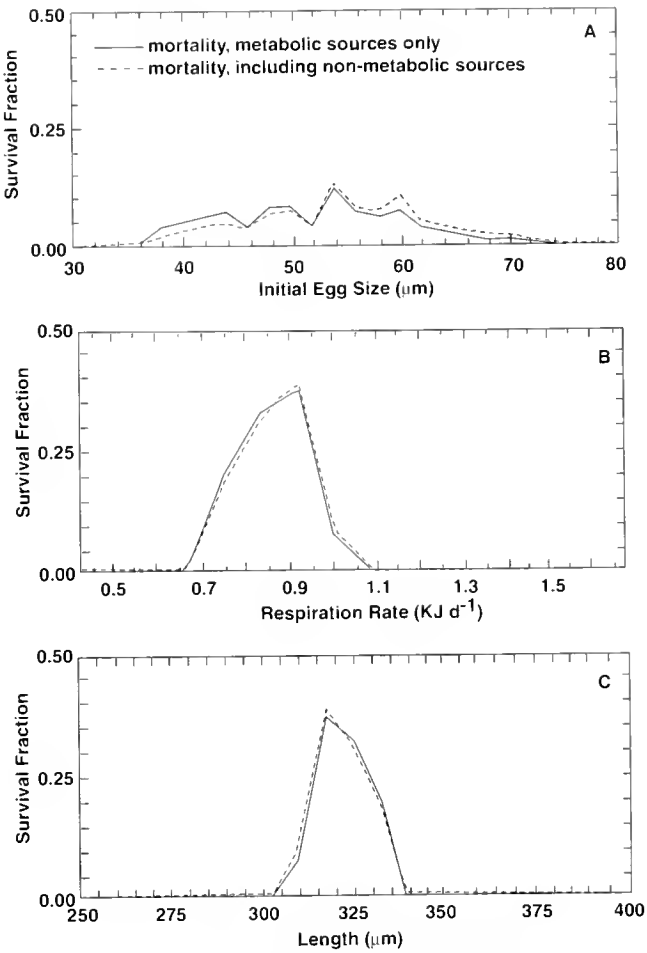

Figure 20. Simulated *Crassostrea gigas* larval survival as a function of (A) initial egg-size, (B) base respiration rate, and (C) larval length at metamorphosis obtained when metamorphosis occurs when neutral lipids are greater than 110% of polar lipid. survival times were similar to those observed for starved larvae (His & Seaman 1992, Laing 1995). Survival times of simulated larvae starved after day 4 were two to eight days, with most dying within two days. Larvae starved after day 9 survived two to ten days, with most dying in the first four days. Thirty-three percent of larvae starved after day 14 completed metamorphosis. These were larvae that came from relatively large eggs with low base respiration rates (Fig. 23B). Such larvae were much closer to metamorphosis on day 14 when starvation began than other larvae and were able to complete metamorphosis using their energy stores.

This last simulation is particularly interesting because a narrower range in egg size produced successful larvae. In other simulations, varying base respiration rate was much more significant in determining survival than varying egg size. The simulation supports the conclusion of Gallager et al. (1986) and Gallager and Mann (1986b) that egg quality is important in minimizing losses due to low food supply during larval life.

Genetics of Egg Size and Respiration Rate

As discussed previously, it was necessary to model larval cohorts characterized by a range of egg sizes and growth efficiencies to obtain the observed ranges in larval life span, size at metamorphosis, and survivorship seen in experimental studies of *C. gigas* larvae. One important choice, then, was the mean of the frequency distribution chosen for these two variable characters.

The average egg size was taken to be 50 μm in the reference simulation. With a few exceptions, varying the conditions of the simulation did not vary the range of viable egg sizes to a great degree (Figs. 9–22). The range of viable egg sizes is dictated by the most basic constraints imposed by biochemical composition at birth and by environment (e.g., food supply) rather than by genetics. Not surprisingly, changing the initial egg distribution so that it is centered on a 60 μm egg, rather than a 50 μm egg, results in survivorship that is skewed toward larger egg sizes (Fig. 24A versus 9A) because most eggs of 40 to 70 μm in size are viable

TABLE 4.

Total population survivorship for simulated cohorts of *Crassostrea gigas* larvae in which successful metamorphosis occurs when neutral lipid reserves exceed by a given fraction the polar lipid content.

Salinity	15	20	25	30	35
Cohort survivorship	0.0%	33.1%	63.3%	62.4%	31.8%

(Fig. 9), and moving the average size higher simply increases the total number of eggs spawned in this higher size range. Respiratory effects on survivorship (Fig. 24B) are not altered by a change to mean egg size. However, the larval length at the time of metamorphosis is somewhat larger (Fig. 24C). Total survivorship declines somewhat from 64% to 60% because more of the cohort that is spawned falls into egg sizes above 70 µm. Overall, however, the simulation shows that a moderate change in mean egg size does not materially change the outcome of the simulation. As the simu-

lation depicted in Figure 23B shows, this outcome may not be repeated in cases of nonsaturating food supply.

Average base respiration rate for larvae was set at 1.05 KJ day^{-1}. Increasing the mean base respiration rate by 20% to 1.25 KJ day^{-1} results in larval survival skewed toward lower respiration rates (Fig. 25B) and smaller egg sizes (Fig. 25A), with a rapid decrease in survival above respiration rates of 1.05 KJ day^{-1} and egg sizes above 60 μm. Larval survival peaks at a metamorphosis length of 308 μm, which is similar to that obtained in the reference simulation (Fig. 9C). However, larval survivorship decreases rapidly for larger larvae (Fig. 25C). Total survivorship declines dramatically from 64% to 33%. Higher base respiration rates penalize larger larvae because insufficient excess neutral lipid can be obtained under the food supply provided to cover tissue maintenance and provide the requisite energy stores for metamorphosis. Thus, the model is considerably more sensitive to moderate changes in base respiration rate than in mean egg size. Conversely, the influence of environment on the range of viable base respiration rates is much greater than on the range of viable egg sizes and, so, a change in mean respiration rate might easily produce an alternate result under different environmental conditions.

DISCUSSION

Perspective

The model described here is unique in that it seeks to recreate many of the growth and mortality phenomena observed in *C. gigas* larvae from basic biochemical principals. The approach was dictated by a desire to model the influence of food quality and short-term changes in food supply on larval growth and survival and the influence of egg size and composition on ultimate success at metamorphosis.

Although biochemically based, the model contains only the crudest biochemical constructions. The larva is modeled as a four-constituent organism composed of protein, carbohydrate, neutral lipid, and polar lipid. Each constituent and the transitions between constituents are modeled using the simplest of flow schemes. So, for example, lipid and carbohydrate are interchangeable, carbohydrate covers respiratory demand when in sufficient supply, and

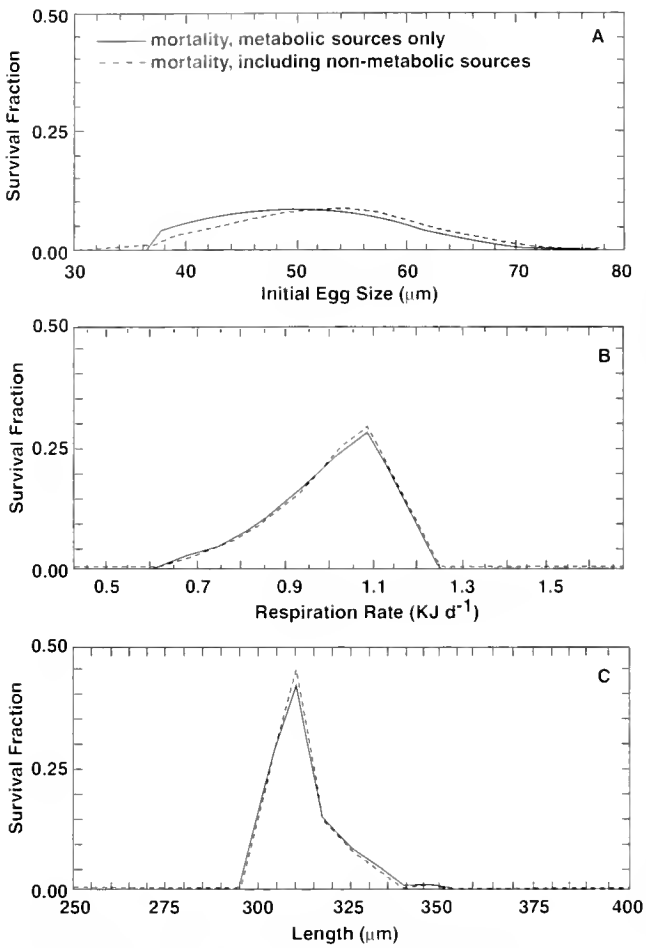

Figure 25. Simulated *Crassostrea gigas* larval survival as a function of (A) initial egg size, (B) base respiration rate, and (C) larval length at metamorphosis for a base respiration rate distribution that is centered at 1.254 KJ day^{-1}. The simulation used the reference case environmental conditions given in Figure 9.

neutral lipid is the primary storage component. Assimilated protein is used only to create tissue protein, and this necessitates the formation of a certain amount of structural carbohydrate and polar lipid. Failure to supply these other components in the amounts required by protein assimilation results in structural imbalances and eventually death. More complex biochemical transformations are excluded. So, for example, although many amino acids can be synthesized, protein, in the model, comes only from protein ingested as food, with the one exception early in larval life when neutral lipid is used to sustain growth in the first few days after birth. Carbohydrate and protein, though potentially used as energy reserves for metamorphosis or to sustain the larva during periods of negative scope for growth, are only used as the last resort and, then, only in proportion to their fractional contribution to structural tissues.

Although based on a simplistic biochemistry, the model succeeds in simulating some of the basic observations of *C. gigas* eggs and larvae, suggesting that simple biochemical constructs can be successful and may encompass the biochemical transitions most prominent in determining cohort success. Verifications of many of the details in the simulations cannot be accomplished because of limited information on the details of larval biochemical composition as it is influenced by environmental and genetic factors. Nevertheless, the model succeeds in simulating known population-level characteristics that permit verification at this higher-order level of integration.

Necessities of Model Construction

A number of special model constructs were required to obtain verifiable simulations. These included resolving a mismatch between egg ash content and earliest larva ash content, the conversion of egg size to earliest larval size, the addition of genetic variation, and the need to modify filtration rate, especially in early stage larvae.

Birth and Condition

Condition is tracked in the model using a protein-to-ash ratio. Tracking condition was necessitated by the desire to model periods of low food supply, including, in the extreme, periods of starvation. Particularly once the shell is formed, larval size does not change during periods of restricted food supply, but larval tissue weight does (Laing 1995).

The protein-to-ash ratio for eggs is high and does not fit the larval pattern. Hence, initializing the model with the protein-to-ash ratio of the egg consistently failed to produce verifiable simulations. Presumably, as the egg develops and hatches, ash is added from inorganic solutes in the surrounding water and the protein-to-ash ratio drops. The model was initialized with the protein-to-ash ratio of newly hatched larvae to circumvent this problem. Reconciling the mismatch between the protein-to-ash ratio of eggs and newly hatched larvae will require additional experimental studies.

Length at Birth

Eggs are more or less spherical. Larvae, even newly hatched, are not. The model tracks length independently of weight, a necessity imposed by the wealth of data for verification provided in terms of length and the need to follow condition. Initializing the model with egg "length" (diameter) fails because the increase in length during egg development is not representative of growth, but simply a result of tissue reorganization. Consequently, a growth model cannot account for this process. We used a conversion from egg diameter to earliest larval length to circumvent this problem.

Genetic Variation

One of the key observations recorded in the literature is the success rate at metamorphosis and the size of metamorphosing larvae. Considerable variability exists depending upon the conditions of larval culture, and egg quality provides a sufficiently strong signal that variations in egg quality should influence success at metamorphosis in simulated spawns. Considerable variability also exists within cohorts. Such variability cannot exist if all larvae in the cohort are equivalently affected by environmental conditions. Consequently, it was necessary to add some variation between larvae to the model.

The observations of Gallager and Mann (1986a) and Gallager et al. (1986) provide a basis for describing a range of egg sizes with a simple Gaussian function to define the frequency of a given egg size in a cohort. This range in egg sizes also produced a range in egg qualities in that larger eggs were relatively more lipid rich. The resulting simulations showed an improved fit to observation in

that a range of larval sizes and success rates at metamorphosis were obtained.

However, the range in predicted larval size and success at metamorphosis was still too constrained in comparison to observation. The obvious next option was to include a range of growth efficiencies. Genetic variation in growth efficiency is well described and may accrue from any number of processes including variations in respiration rate, protein turnover, assimilation efficiency, or feeding efficiency (e.g., Garton 1984, Koehn and Hilbish 1987, Garton & Berg 1989, Koehn & Bayne 1989, Garton & Haag 1991). In the model, respiration rate and filtration rate control growth efficiency and, although the two processes are somewhat differently affected by temperature and salinity, inserting variation in either effectively generates simulated larvae with a range of growth efficiencies. Genetic variation in growth efficiency was inserted as a range in base respiration rates using a simple Gaussian construction. This addition produced the range in outcomes at metamorphosis expected from observation.

Simulations were run to examine the influence of varying the mean of the Gaussian distribution describing egg size and respiration rate. Simulations did not change markedly with a variation in egg size because the range of viable egg sizes was tightly constrained, as discussed later. The model was more sensitive to variations in the mean base respiration rate. Here, however, simulations showed that little leeway existed for varying the central tendency of base respiration rate because substantial changes in cohort survival occurred with relatively small changes in central tendency.

These results are compared, for the most part, to observations taken under saturating conditions of food and near-optimal environmental conditions. Optimal base respiration rates, to a large extent, and egg sizes, particularly under limiting food supply, suggest that changes in the range of egg size and base respiration rate might be adaptive in certain cases that might routinely exist under field conditions. One might expect variations in respiration rate (=growth efficiency) to be the most adaptive.

Filtration Rate

Measured filtration rates always provided growth rates higher than observed. The mismatch was largest for smallest larvae. In these animals, observed reductions in neutral lipid clearly indicated that assimilation does not provide adequate resources to explain observed growth, although measured filtration rates would indicate otherwise. It seems likely that filtration rate and ingestion rate are not equivalent in larvae or that assimilation efficiency is size-dependent.

In the model, a size dependency on ingestion rate or assimilation efficiency is effectively equivalent, so no attempt was made to distinguish between the two. One might reasonably conclude that both feeding and digestion should be affected by larval development processes, particularly during early larval life, and that this might lower the amount of energy realized at a given filtration rate. One might also conclude that filtration efficiency in part is a function of the larva's use of the vellum to maintain its position in the water column as well as to feed and, so, particularly under conditions of saturating food supply where most filtration rates are measured, a tendency to filter more material than can be ingested should exist. Regardless of the cause, to lower growth rates from levels predicted from observed filtration rates, we imposed a size-dependent penalty on ingestion that was largest for the smallest larvae. The mismatch between observed growth rates and simulated growth rates from measured filtration rates, however, points to an area of early larval biology that warrants further study.

Metamorphosis

The simple biochemical construction of the model required a simple explanation for the metabolic basis for triggering metamorphosis. A full explanation of how endogenous and exogenous factors control metamorphosis (e.g., Coon & Bonar 1986, Fitt et al. 1990, Berias & Widdows 1995) does not exist. Accordingly, the approach used was derived within the limitations imposed by the four-pool biochemical construct of the model and five observations in the literature that directly related to it. (1) Filtration rate drops in larvae of about 250 μm and larger, probably due to changes in either behavior or the beginnings of tissue reorganization that must presage metamorphosis. The former option would be sufficient. Older larvae spend more time near the bottom (e.g., Dekshenieks et al., 1997) and, thus, may spend less time filtering, a fact that would be interpreted in experiment as a decline in filtration rate. The reduction in feeding rate should ultimately reduce larval scope for growth, and this should have consequences concerning the decision to metamorphose. (2) Smallest size at metamorphosis is about 275 μm. This size should be somewhat larger than the size triggering the decline in filtration rate. (3) Lipid stores decline at metamorphosis. This could be a consequence of a decline in scope for growth as well as a consequence of the energy needed to reorganize tissue. (4) Literature information suggests that larvae require a certain amount of stored energy to metamorphose successfully. Although any kind of tissue constituent might provide this energy, the reliance of larvae on neutral lipid as the primary energy store suggests that the proportion of neutral lipid is a good measure of energy available for metamorphosis. (5) The quantity of lipid present in the egg influences larval survival. Thus some information on the status of neutral lipid reserves should pertain to the decision to undergo metamorphosis.

The process of metamorphosis was modeled using these five observations to generate explicit triggers for certain steps in the process, as follows. (1) Larvae were assumed to become potentially competent to metamorphose at 275 μm, following a decrease in filtration rate at 250 μm. Simulations showed that the filtration rate decline could not be set at 230 μm or 275 μm. The minimum size for metamorphosis, in most simulations, did not fall below 285 μm, so that the 275 μm size limit was rarely invoked. That is, invoking a change in filtration rate at 250 μm normally resulted in larvae metamorphosing at sizes above 275 μm. (2) Larvae were assumed to become competent to metamorphose when a daily decline in neutral lipid of a certain level occurred. Our assumption was that larvae might be expected to continue to grow and store lipid as long as a sufficiently positive scope for growth was present and this would enhance success, but that a decline in neutral lipid would reduce success. Accordingly, metamorphosis should occur when scope for growth dropped significantly below zero. The range of observed sizes at metamorphosis suggests that some process of this sort does occur. Although the decline in filtration rate at 250 μm predestined larvae to eventually reach the trigger point defined by a significant neutral lipid decline, food quantity and quality and biochemical composition can permit growth much in excess of 250 μm before scope for growth drops to substantially negative values. Typically, in the model, metamorphosis occurred at sizes of 300–330 μm, as observed in culture. (3) Larvae were

assumed to metamorphose successfully if neutral lipid supplies were adequate. Adequacy was judged as a ratio between energy stores and structural components.

We cannot evaluate how accurately the modeled mechanism for metamorphosis approaches reality, not having available an adequate understanding of the biochemistry of the process. However, the simulations reveal some interesting trends. The choice of 250 μm as the point where filtration rate declines is based on observation, but the model also indicates that this trigger is tightly constrained to this size. Neither 230 μm nor 270 μm sizes offered verifiable results. The choice of a 25% daily decline in neutral lipid triggering competency is also tightly constrained. Values of 10% and 40% did not provide results equivalent to observations. Both larval size distributions and success rates at metamorphosis varied from observations. The choice of a ≥1:1 ratio of neutral lipid to polar lipid is also tightly constrained. Values of 0.8:1 and 1.1:1 produce unrealistic size distributions and success rates at metamorphosis.

Verification of this construction for modeling metamorphosis was directed at evaluating performance in simulating four important phenomenon: (1) variations in egg quality significantly influenced success at metamorphosis, (2) variations in food quality and quantity significantly influenced success at metamorphosis, (3) larval life span as predicted was well within the range of observations, and (4) larval size structure at metamorphosis was well within the range of observation. Obtaining these four results requires a reasonably accurate rendition of growth and survival at the biochemical resolution of the model. This suggests that the approach to modeling metamorphosis must reflect, in some significant way, the process as it actually proceeds in the larva.

Consequences of Model Construction

Larval success is determined by intrinsic and extrinsic factors. Intrinsic factors include egg size and quality and genetic makeup. Extrinsic factors include temperature, salinity, food quality, and food quantity.

Implications of Egg Size

Oyster eggs are about 50 μm in diameter, with a size range typically of 40–60 μm. The model identifies viable egg sizes in the range 37–73 μm, very similar to observations. Egg sizes outside this range are predicted to be nonviable due to lipid imbalances in early larval life. Very likely, the lower limit of 37 μm represents a packaging problem. Egg size is simply too small to provide adequate resources for the structural changes required in forming the first larval stage. In the model, the required structural tissue ratios cannot be achieved and still provide any neutral lipid reserves. In effect, the larva is never born. The upper limit of about 73 μm yields a larva that has insufficient neutral lipid reserves to cover metabolic needs immediately post-hatch. During this time, feeding is inefficient, and some of the larva's carbon needs for growth and tissue maintenance must be met by using neutral lipid reserves. The larger larvae, coming from eggs >73 μm in diameter, essentially starve to death before they can become competent filter feeders. This may provide one explanation for the small size of most planktotrophic eggs.

Presumably, the upper limit on egg size could be extended by increasing neutral lipid reserves; however, the bet hedging mode of life (e.g., Stearns 1976) would limit the amount of energy invested in any one embryo. The trade-off between additional energy expenditure and increased success at metamorphosis is clearly indicated in Figures 11, 15, and 23. Larger eggs yield successful larvae over a much larger range of respiration rates and environmental conditions than do smaller eggs. Larger eggs yield larvae that reach metamorphosis faster (shorter planktonic time), thus minimizing loss to predation and the chance of reduced survival from transient reductions in food supply. Thus, the simulations suggest that the average egg size of 50 μm minimizes the chance of reproductive failure, which increases rapidly at smaller egg sizes, while still permitting the spawning of a large number of eggs. As an example, increasing average egg size to 60 μm reduces total egg output by 31% at a given total energy expenditure. An equivalent increase in larval success is not achieved in our simulations.

The model also indicates, however, that transient reductions in food supply during larval life may increase the success rate for large eggs relative to small eggs. In this circumstance, the extra energy required to produce large eggs may be better repaid. Whether an increase in fitness is adaptively advantageous requires a better understanding of food supply under field conditions and how this influences larval survival.

Respiration (=Growth Efficiency) Effects

In the model, varying respiratory rate is equivalent to varying growth efficiency. Larvae with high growth efficiency have low respiration rates. The model identified an upper and lower limit to growth efficiency under defined environmental conditions. The upper limit varies widely depending upon environmental conditions, whereas the lower limit is relatively fixed. Simulations show that the upper limit on base respiration rate (e.g., ~1 kJ day^{-1} in Fig. 9) is determined by the point at which larvae cannot acquire sufficient neutral lipid stores to successfully metamorphose. Smaller eggs are also less viable because insufficient neutral lipid can be stored to cover larval needs over a few days post-hatch. Interestingly, very low respiration rates also normally result in unsuccessful larvae. These animals put too much assimilated carbon into somatic structural tissue and so have insufficient neutral lipid reserves. We are unaware of experimental data upon which to verify this last result.

Condition and Mortality

Many models do not explicitly follow length and weight independently (e.g., Powell et al. 1992, Dekshenieks et al. 1993). In bivalves, tracking condition permits observation of larval performance during periods of low food supply. This requires tracking length and weight independently such that not all increases in weight result in changes in length and such that no decreases in weight result in decreases in length. The performance of the model was evaluated under conditions of food deprivation by simulating the process of starvation. Although the mechanisms of death under these conditions are described in the model, death occurs due to a variety of biochemical imbalances, depending upon the initial status of the larva. Whether such a degree of complexity actually exists requires more information on the changes in larval biochemical composition under conditions of low food supply. However, the higher-level effects that integrate biochemical processes

were simulated by the model, including a decrease in weight (condition), a drop in neutral lipid content, a nonlinear time-dependent increase in mortality, and the still-successful metamorphosis of older larvae.

In addition to inadequate food supply, larvae can die if food of inadequate composition is ingested. Thus, rigorous criteria were set for biochemical compositions not allowed in viable larvae. Food having inadequate lipid or being too protein-rich resulted in mortality, even if the quantity of food remained high. These parameterizations describing mortality under such conditions are essentially *ad hoc* constructs (literature observations not being available), but they did produce cohort mortality rates that appeared to be realistic.

Effect of Diet

Most experimental studies on *C. gigas* larvae have used food supplies of ≥ 2 mg L^{-1}. This level of food saturates feeding and, in fact, raising food quantity from 2 mg L^{-1} to 4 mg L^{-1} in the model has little influence on simulated larval success. However, as in *Crassostrea virginica* (Dekshenieks et al. 1993), food quantities below 1 mg L^{-1} dramatically restrict larval growth and survival. As food supply declines, animals with high growth efficiencies are selected for in the model. At high food content, larger eggs with lower growth efficiencies also survive to metamorphosis. With rare exceptions, small eggs with low growth efficiencies never do. Thus, the influence of growth efficiency is nonrandomly distributed across egg size, and the influence seems to be mediated in part by food quantity and to a larger measure by food quality.

The influence of food content on *C. gigas* larval growth and survivorship has received considerable attention (e.g., Wilson 1978, Waldock & Nascimento 1979, Helm & Laing 1987). Although not all studies agree, low-protein diets and high-lipid diets often show improved growth and survivorship. The simulations show the positive effect of a low-protein diet on larval growth and survivorship. With this diet, a relatively larger portion of ingested energy is allocated to energy stores that in turn sustain the larva through metamorphosis. With a high-protein diet, larvae grow too fast and fail to store enough energy to sustain them through metamorphosis. The destination of protein within the larva is limited in terms of building tissue and covering metabolic needs (Table 2) if insufficient carbohydrate is ingested. Any transfer of excess amino acid into other tissue components is not permitted. Potentially, this allocation of ingested protein is too simplistic, although the simulations do provide some insight into the value of a low-protein diet.

Simulations with no neutral lipid gave similar results in terms of larval survivorship and growth. Thus, the relative amounts of protein and neutral lipid in larval food are important determinants of growth and survival.

A number of studies have identified specific components of the lipid pool as important dietary constituents (e.g., Thompson et al. 1994, 1996). The model could be expanded to track more complex biochemical pools such as polyunsaturated fatty acids (PUFAs) or sterols. The fact that the model achieves realistic simulations over a relatively wide range of environmental and dietary conditions indicates that the approach used to model larval biochemistry, including the subsuming of a diversity of lipid compounds into two pools, polar and neutral, is sufficient to provide realistic simulations of larval growth, metamorphosis and survival.

Temperature and Salinity

C. gigas is known to be relatively stenotopic for the genus. Temperature and salinity conditions describing optimal growth circumscribe a narrow range. The model reproduces this behavior. In this contribution, most simulations were run under optimal conditions of 25 C and 30‰. Lower temperatures result in insufficient neutral lipid storage and metamorphosis because feeding rate is low. Temperatures above 30 C result in biochemical imbalances due to high respiratory demand. Low salinity also results in insufficient food ingestion to meet the demands of metamorphosis. Again, data to verify the accuracy of predicted cause and effect on biochemical composition are not available.

Growth rate is a complex function dependent upon the balances of ingestion and respiration. The ability of positive environmental conditions to offset a reduction in food supply and vice versa depends upon the relative scaling of their affects on respiration and ingestion. Thus, increased temperature can "spare" a reduction in food, permitting the same growth rate, if the influence of temperature on ingestive processes scales with a larger exponent than the influence of temperature on respiration. The importance of differential scaling in the energy balance of bivalve molluscs and other animals is well known (e.g., Newell et al. 1977, Powell et al. 1992, Brown et al. 1993). Given the sensitivity of growth and survival to decreases in food supply, the fact that a decrease in food supply often occurs during summer months in *C. gigas* habitat (Kobayashi et al. 1997, Hyun et al., in press), when an increase in temperature is likely to be of significance in increasing ingestion rate, suggests that the differential scaling of ingestive processes and respiration is likely of significance for the reproductive success of the species.

CONCLUSIONS

A model that simulates the growth, development, and metamorphosis of *Crassostrea gigas* larvae has been developed. The model is the first of its kind in that it (1) tracks length separately from weight so that changes in condition can be followed and (2) predicts growth from the ingestion and transformation of biochemical constituents, thus permitting the simulation of the effects of changes in food quality. Food quality and feeding rate are important constraints in larval culture, so the model might be used to optimize culture conditions for *C. gigas* larvae as well as to investigate the influence of critical periods of food supply in larval development in the field. Of particular importance is the investigation of "teleconnections" during larval life in which events occurring at one point in larval life have consequences at another, temporally distant, point. The model has a crude depiction of the biochemistry of *C. gigas* larvae. However, the model works well even with this limited biochemistry and indicates that the formulation of sophisticated biochemically based models offers the promise of substantially improving the population modeling of marine larvae.

BEHAVIORAL RESPONSES OF VELIGER LARVAE OF *CRASSOSTREA GIGAS* TO LEACHATE FROM WOOD TREATED WITH COPPER-CHROME-ARSENIC (CCA): A POTENTIAL BIOASSAY OF SUBLETHAL ENVIRONMENTAL EFFECTS OF CONTAMINANTS

ANGELIKA PRAËL,[1] SIMON M. CRAGG,[1]* AND SUZANNE M. HENDERSON[2]

[1]*Institute of Marine Sciences, School of Biological Sciences, University of Portsmouth, Ferry Road, Portsmouth PO4 9LY, United Kingdom;* [2]*Forest Products Research Centre, Buckinghamshire Chilterns University College, Queen Alexandra Road, High Wycombe HP11 2JZ, United Kingdom*

ABSTRACT This study examined effects upon swimming behavior of larval oysters (*Crassostrea gigas*) caused by leachates from timber treated against marine borer attack using CCA (copper, chromium and arsenic bound to the lignocellulose of the wood cells). Early veliger stage larvae were observed to avoid a layer of concentrated leachate. No effect of more dilute leachate on swimming behavior of 2-day-old larvae was detected, but 3- and 7-day-old larvae swam two to three times faster in leachate than in plain seawater and moved up and down more in leachate. The concentrations of leachate used in these experiments considerably exceed likely environmental levels, but behavior could be used to assay improvements to the treatment process and to provide data for models of the impact of treated wood structures. The methodology offers a bioassay for assessment of sublethal effects of toxicants.

KEY WORDS: CCA, veliger, swimming behavior, bioassay, copper, chromium, arsenic

INTRODUCTION

Veliger larvae of bivalves display patterns of swimming behavior that maximize their chances of remaining within the optimum region of the water column for feeding and dispersal. They swim up vertically orientated helices, intermittently ceasing swimming and sinking before resuming upward swimming (Cragg, 1980). Changes in swimming velocity and the frequency of alternation between swimming and sinking occur in response to environmental variables such as salinity, temperature and pressure (Hidu & Haskin 1978, Cragg 1980, Tremblay & Sinclair 1988, Mann et al. 1991, Dekshenieks et al. 1996). Responses to sublethal levels of toxicants have also been reported. Veligers of *Crassostrea gigas* show a greater tendency to swim near the surface of containers in water contaminated with mercury (His et al. 2000) or in water overlying contaminated sediment (Van den Hurk 1994). Contaminants may also affect overall levels of activity of bivalve veligers in experimental chambers (Chang et al. 1996, Thompson et al. 1997). In their review of bioassays using bivalve larvae, His et al. (2000) draw attention to the potential of using swimming activity in bioassays as a means of detecting sublethal effects of toxicants. The current study was designed to develop such a bioassay. It was performed as part of a larger investigation designed to evaluate the effects of leachate, from biocide-treated wood, on the marine environment (Cragg 1995).

To protect submerged wood in marine structures from rapid and severe biodegradation (mostly due to boring invertebrates) it is impregnated under pressure with biocides such as copper-chrome-arsenic (CCA) (Eaton & Hale, 1993). After treatment and prior to drying, the components of CCA are allowed to react with the lignocellulosic components of the wood to form insoluble compounds, a process known as fixation (Anderson et al. 1991. Though the treatment is resistant to leaching, detectable amounts of the elements in the treated wood enter the environment when placed in seawater (Hayes et al. 1994, Lebow et al. 1999). In recent years, evidence has been presented that in marine environments, leachate from CCA-treated wood can have a range of effects on non-target species dwelling on or near the wood (Weis & Weis 1992, Weis & Weis 1993, Weis et al. 1993). However, other field studies using bioassays suggest that in environments with sufficient tidal water exchange, effects are likely to be short-lived and localized (Wendt et al. 1996). The mathematical model of Brooks (1996) also highlights the importance of taking account of water exchange rates when predicting environmental effects of leachate from CCA-treated wood. The value of such models is dependent on adequate information about the toxic effects of particular concentrations of toxicants.

Measuring total element concentrations alone is not enough to predict biological effects, and bioassays give a better measure of the bioavailability of the element (Chapman & Long 1983). Furthermore, single metal studies are not adequate for predicting the effect of a leachate that may contain three toxic elements, but bioassays permit the detection of any synergistic effects between elements. Field observations have shown that the presence of elevated levels of the elements investigated in this study may modify settlement behavior of invertebrates (Weis & Weis 1992, Brown et al. 2000). In this study the potential of these elements to modify swimming behavior was investigated. This article summarizes findings from a number of experiments performed in order to determine optimum conditions for a bioassay using swimming behavior as the measurable response.

MATERIALS AND METHODS

Preparation and Analysis of Leachate

Sapwood blocks of Scots pine (*Pinus sylvestris* L.) with unsealed crosscut faces were impregnated with copper-chromium-arsenic (CCA) solutions by the Bethell vacuum-pressure process (Eaton & Hale 1993). The CCA solutions were made from formulations containing these elements either only as oxides or as salts (Celcure AO and Celcure A respectively, Rentokil UK). Retention of CCA was calculated from the gain in block weight due to solution uptake and the concentration of solution used. The treated wood was kept in non-drying conditions for at least seven days to permit fixation reactions between the lignocellulose complex of the wood and the treatment chemicals to take place. The blocks were then dried to below fiber saturation point. Blocks used for

*Corresponding author. E-mail: simon.cragg@port.ac.uk

preparation of leachate were selected from those with solution uptakes typical for well-treated wood.

For initial experiments, leachates were prepared by grinding wood blocks (50 × 30 × 25 mm, untreated or treated to retentions of 12, 26 and 47 kg m^{-3} CCA) to sawdust then agitating the sawdust frequently by hand for seven days in 250 ml of seawater at room temperature. Leachates produced from 6 blocks of the same original retentions were pooled prior to use in experiments. These leachates were obtained under conditions that were intended to generate unnaturally high leachate concentrations to first establish whether a swimming response was detectable.

Leachates for the main experimental series were generated in a manner that more closely resembled processes that occur under field conditions. They were prepared by immersing treated and untreated blocks in agitated seawater of approximately 34‰ (obtained from Langstone Harbour, Portsmouth, UK) for 24 hours at 24 ± 1°C. The volume of seawater used varied according to the size of block (Table 1). Agitation was achieved by means of an orbital shaker operating at 120 rev min^{-1} or a magnetic stirrer. After 24 hours of agitation the leachates were retained for experimental use (these are referred to in the subsequent account as 1st day leachates) while the wood blocks were resubmerged for a further 24 hours in fresh filtered seawater to produce the 2nd day leachate. Full details of conditions for leachate production are summarized in Table 1.

A 50-ml sample of each leachate and of uncontaminated seawater was acidified with 2 ml of concentrated Analar grade nitric acid. The leachate samples were analyzed for concentrations of copper and chrome using atomic absorption spectrophotometry (AAS) with polarized Zeeman background correction and an acetylene/compressed air flame. The average of the two measurements that were taken per sample to the nearest 0.01-ppm are presented in Table 1. The analytical method proved incapable of providing reliable measurements of arsenic concentrations.

Larval Rearing

Initial experiments were performed using larvae of *Crassostrea gigas* (Thunberg), ranging in lengths between 90–128 μm, taken from cultures at the IFREMER Mus de Loup laboratory.

For the main experimental series, two- and three-day-old larvae of *C. gigas* were obtained from separate fertilizations with gametes stripped from adults supplied by Guernsey Sea Farms. In each case, gametes were obtained from a single pair of adults. The embryo production methodology for UK Environment Agency toxicity assessments (Anon, 1996) was used. The zygotes were reared without food, in seawater from the hatchery that supplied the adults. The unfed D-shaped veliger larvae, which were 48h-old at the time filming began, measured 80–90μm in length while the 72h-old larvae measured 100–120 μm.

A third set of *C. gigas* larvae were shipped overnight by courier from Seasalter Shellfish Hatchery, Cumbria, U.K. The larvae arrived wrapped in chilled moist filter paper and were slowly warmed to room temperature then resuspended in aerated, filtered Langstone Harbour seawater. The water temperature was then maintained at 24 ± 1°C—the hatchery rearing temperature. At the time filming of these larvae began, they were seven days old and measured 170–180 μm in shell length.

Observations of Larval Swimming Behavior

In the initial experiments, larvae in 3.5 ml of seawater taken from rearing tanks were placed in a 5-ml cuvette and left five minutes to acclimate. Swimming behavior was filmed, under normal laboratory lighting, within a marked 5-mm vertical distance for five minutes prior to the gentle addition of a 20, 50 or 100μl sample of leachate to the water surface. Swimming activity over 5 minutes was recorded using a video camera with a macro zoom lens.

In the main experimental series, acrylic 4.5-ml spectrometry

TABLE 1.

Details of age of *Crassostrea gigas* larvae observed and of the concentration of copper and chromium (ppm, mean ± SD) in seawater to which they were exposed. The seawater was either obtained from the oyster hatchery or was locally derived and in some cases modified by leachate from the first or second day of immersion of a wooden block with or without treatment by salt or oxide formulation of CCA.

cuvettes (ELKAY ultra VU) were filled with 2 ml of leachate and 2 ml of the seawater in which the larvae had been reared. This contained sufficient larvae to provide subjects for filming without causing abnormal behavior due to overcrowding. Larvae were exposed to first or second day leachates and compared to control larvae swimming in cuvettes containing seawater without leachate. Five replicate cuvettes were prepared for each treatment. Details on types of leachates investigated are given in Table 1.

The cuvettes were illuminated with a fiber-optic source from the side and larval behavior was filmed against a black background using a color video camera (JVC TK1381) with a macro zoom lens. The lens was zoomed and focused so that either the whole length of the cuvettes was visible, or that the width of the visual field was filled with two adjacent cuvettes. The recorded image included a scale for measurement of parameters of larval swimming paths. Larvae were acclimatized to conditions in the cuvette for 30 minutes prior to recording two-minute film for each cuvette. Further filming of the same cuvettes was conducted at intervals for up to one day. Filming was conducted at 22 ± 2°C.

Measurements of the following three variables were made from projections of the video recordings on a flat screen:

1. the total number of swimming larvae;
2. the percentage of the total number of larvae within the cuvette ascending and descending per minute through a horizontal line 20 mm from the bottom of the cuvette;
3. the vertical velocity over 1 mm of ascending larvae.

Statistical Analysis

Data relating to larvae of different ages were analyzed separately as the leachates used at different ages were not directly comparable. Transformed data on activity and velocity were analyzed by GLM using adjusted SS in the tests. Plots of residuals and Levene's test for heterogeneity of variance revealed no evidence of departure from the assumptions of ANOVA tests. Tukey or Tukey Kramer tests were applied to pair-wise comparisons to determine the sources of significant differences in the factors. Activity data were transformed by taking square roots of arcsin transformed percentages and analyzed in a model using leachate type and period of leaching as fixed factors. Velocity data were transformed by taking natural logs and analyzed in a model using type of leachate as a fixed factor and cuvette replicate as a random factor. All statistical tests were performed with Minitab version 12.1 (Minitab Corp.)

RESULTS

Copper concentrations were below levels of detection (<0.01 ppm) in hatchery water, Langstone Harbour seawater and leachates from untreated wood blocks. Chromium concentrations ranged between 0.17 and 0.24 ± 0.01 ppm in all samples that contained hatchery water. Concentrations of Cu and Cr in leachates from treated wood were generally lower in 2nd day leachates than in 1st day leachates, but there was no clear correlation between CCA retention, block surface area or leaching volume and metal concentration in the leachate (Table 1). Much higher levels of chromium were found in the leachate from wood treated with the salt- than the oxide-type CCA.

In the initial experiments, larvae were observed to swim in a normal vertical helical pattern within the cuvettes. Those encountering a surface leachate layer derived from the addition of 100 µl of leachate obtained from blocks treated to 47 kg m^{-3} CCA stopped then sank before resuming upward swimming. During the 5-minute filming period, their activity decreased until, at the end, most larvae were inactive. Samples of leachate from blocks treated to 12 and 26 kg m^{-3} CCA produced less pronounced effects, although larval swimming activity still decreased over time. No effect on normal helical swimming behavior was detected within the filming period, in cuvettes where leachate from untreated wood was added.

In the main experimental series, leachate type had a significant

effect on levels of activity in 2-, 3- and 7-day larvae, but no difference could be detected between the effect of 1st and of 2nd day leachate (Tables 2 and 3). Three- and 7-day-old larvae exposed to CCA-oxide leachate were two to three times as active ($p < 0.005$) as those in water not exposed to treated wood (Fig. 1). Most 2-day-old larvae concentrated near the surface, so activity recorded lower down cuvettes was low. Differences between activities in the different types of leachate of these larvae were small but, in the case of the difference between activity in leachate from CCA-oxide treated wood and that in leachate from untreated wood, significant ($p = 0.033$).

Larvae in the cuvettes continued to be active for at least a day after initiation of the experiments, except in the case of 7-day-old larvae exposed to CCA-oxide leachate, which became totally inactive after 24h. The significantly higher activity of 3-day-old larvae was no longer evident three hours after the larvae were introduced to the leachate.

While the 2- and 7-day larvae in seawater without leachate had similar mean upward swimming velocities (0.32 and 0.31 $mm.s^{-1}$ respectively), three-day larvae were much slower (0.22 $mm.s^{-1}$) (Fig. 2). There was no significant difference between the velocities of 2-day-old larvae in seawater alone and in seawater with various leachate types, but in the case of 3- and 7-day larvae the presence of leachate resulted in significantly higher swimming velocities ($p < 0.05$) (Table 3). Three-day-old larvae subject to CCA leachate swam 1.4 times faster than those in leachate from untreated wood and 2.7 times faster than those in hatchery water. Seven-day larvae subject to CCA leachate, swam on average twice as fast as those in uncontaminated seawater. Significant cuvette to cuvette variations in mean swimming velocity occurred, accounting for 33%, 11% and 12% of variance in the case of 2-, 3- and 7-day-old larvae respectively.

DISCUSSION

The Nature of Leachates

The analytical data from the leachates indicate that the rate of leaching of copper and chromium from treated wood generally decreased with time. This is consistent with findings of other studies of leaching into seawater from CCA-treated wood (Albuquerque et al. 1996). Studies to date suggest that the rate of leaching declines exponentially and that this is true for all three elements (Brooks 1996, Cragg et al. 2001). Factors such as the retention of preservative, the surface area of wood exposed to the water, the proportion of exposed wood surface that consists of cross-cut wood cells and the volume of water used all affect the concentration of metals in the leachate (Cragg et al. 2001). In this study, the use of small leaching volumes, of a high proportion of cross-cut surfaces and of temperatures at the upper end of the range likely to occur in the environment, will have lead to concentrations of leached elements exceeding the worst case scenario proposed by Brooks (1996).

The chromium concentrations measured in the hatchery water (0.17 ppm), greatly exceed the expected chromium concentration of uncontaminated seawater of 0.003 ppm (Brooks 1993). The elevated chromium levels may indicate the presence of stainless steel somewhere in the hatchery water system. The experimental design did not permit the isolation of this effect on the larvae from other factors.

Larval Responses to Leachate

Control larvae swam at velocities somewhat lower than those reported for other oyster veligers, 0.37 to 3.10 mm s^{-1} depending on age and conditions (Mann & Rainer 1990). This may reflect the small size of the experimental chamber, but Mann and Rainer demonstrated that only at oxygen tensions less than 20% of saturation were rates of swimming significantly lower.

Toxic effects of high concentration leachates were evident in the decreasing activity of the larvae in the initial experiment and in 7-day-old larvae in the main experimental series. The initially higher swimming activity by 3- and 7-day-old larvae in the presence of CCA leachates might be due to a stimulatory effect of Cu on cell physiology, a direct physiological response, rather than a behavioral response mediated by the nervous system. Evidence that such effects may occur is provided by the increased the rate of

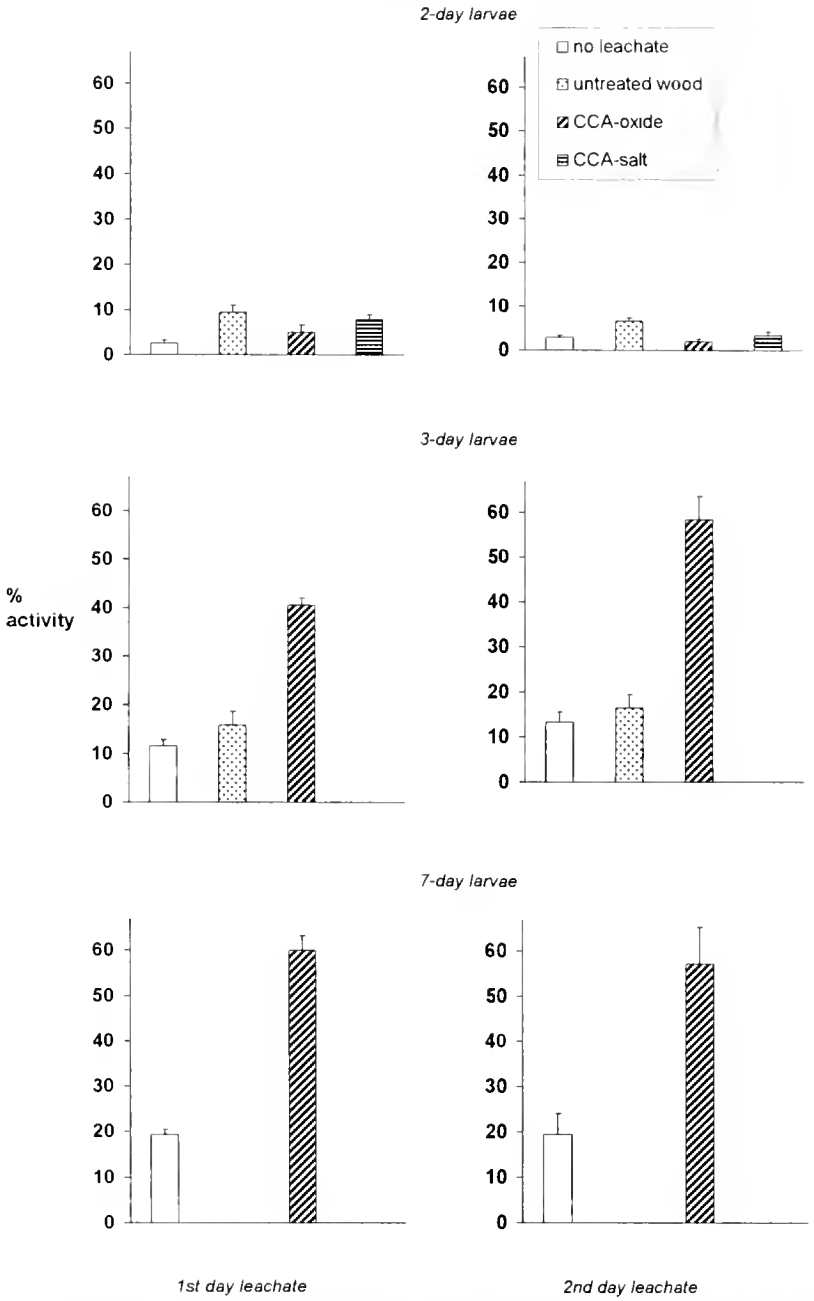

Figure 1. Activity of 2-, 3- and 7-day-old *Crassostrea gigas* veliger larvae in cuvettes containing seawater with or without leachate from wood blocks. Leachate obtained after the first or second day of immersion of the blocks. The blocks were with or without treatment by CCA salt or oxide solutions. Numbers of larvae ascending plus numbers descending past a reference line on the cuvettes are expressed as mean + SE of % of the total number of active larvae.

cell cleavage and larval growth observed by Hoare et al. (1995) in *Mytilus edulis* larvae exposed to 8 ppb of copper. However, it is more likely that the increased swimming velocity and the greater overall levels of up and down movement represent kinesis-type responses to inimical conditions. Kinesis responses may also be responsible for the increases in activity and changes in vertical distribution of larvae in response to contaminants observed by Thompson et al. (1997), His et al. (2000) and Van den Hurk (1994). Changes in velocity, activity and vertical distribution may be due to the same response. Increased swimming velocity would result in larvae reaching the surface more rapidly. A larger number of larvae at the water surface is liable to increase the rate of collision between larvae. Larvae that collide tend to perform the fright response, which involves retracting the velum, closing the shell and sinking (La Barbera 1974; Cragg 1980), then resume swimming.

By increased swimming activity, a larva will sample water quality over a greater vertical range and, due to vertical differences in current velocity, also horizontal range. The chance of being moved away from the polluting source is thus increased (Dek-

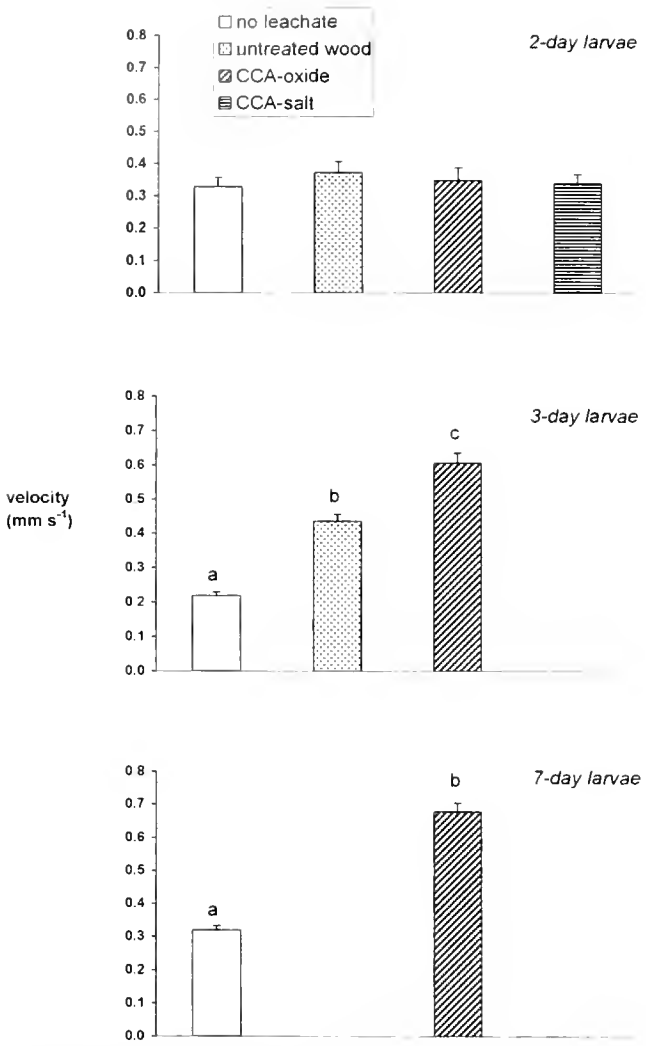

Figure 2. Vertical velocity (mean + SE) of 2-, 3- and 7-day-old *Crassostrea gigas* larvae in cuvettes containing one of four seawater types: seawater alone; seawater with leachate from untreated wood; seawater with leachate from wood treated with an oxide formulation of CCA; seawater with leachate from wood treated with a salt formulation of CCA. Leachate obtained after the first day immersion of the blocks. Significantly different means indicated by different letters (Tukey-Kramer, $p < 0.05$).

shenieks et al. 1996). Further information about the nature of the response would be obtained if larvae were kept in a deeper vessel, permitting investigation of whether larvae tended to sink further before resuming swimming.

The fact that the 3-day-old larvae swam faster in the leachate of an untreated block than in seawater alone suggests that the larvae can detect soluble chemicals derived from the wood itself. Possible candidates include soluble sugars, pectins or the stilbene, pinosylvin, a biocidal compound deposited during heartwood formation in *Pinus sylvestris* (Eaton & Hale 1993).

The lack of a detectable response in the two-day-old larvae may reflect their developmental status. The ability to close the shell appears some time after initial shell formation (La Barbera 1974; Cragg 1980) and the nerve network that innervates the ciliated cells of the velum (Cragg 1989) may not have become functional.

The apparent avoidance behavior of larvae encountering high concentration leachates, observed in the initial experiments, resembles the responses reported by Gruffydd (1976) of veligers of the scallop *Chlamys islandica* exposed to layers of low salinity seawater, and may represent a generalized response to inimical conditions. The avoidance is achieved by the fright response and is probably initiated by stimulation of a sense organ.

Potential for a Behavioral Response Bioassay

The behavioral responses observed in these experiments can be readily measured with simple laboratory equipment and thus have the potential to be used as a bioassay. Behavioral responses are of particular value as bioassays, since they occur at pollutant levels too low to produce clear toxic responses. The results of these experiments highlight the need to include controls for the effect of wood and even for source of water in the assay design. The continued activity of larvae over the day after the initiation of experiments, indicates that the cuvettes provided adequate conditions for the larvae and were thus suitable for a bioassay. By using image acquisition and image analysis software, the increased efficiency of data capture would enable a greater level of replication than in this study, increasing the precision of the assay.

This bioassay could be used to evaluate modifications to treatment procedures designed to minimize in-service leaching. Amongst the modifications worth testing would be the use of a post-treatment, pre-installation leaching in water intended for making up further treatment solutions. Our limited data and more extensive measurements reviewed by Cragg et al. (2001) indicate that rates of leaching tend to decline rapidly. By using pre-installation leaching, the highest emissions of the elements of CCA would be retained for future treatment rather than released to the environment. Modifications to the post-treatment fixation regime may also improve leach resistance, as has been shown by Lebow (1997). Furthermore, Archer et al. (1994) showed that the formulation of CCA used might affect leaching rates, a conclusion supported by the differences in leachate from the salt and oxide formulations used in this study. Minimization of leaching is particularly important where wood is used in aquaculture, such as in buchot culturing of mussels. In view of the concerns raised by Weis and Weis (1996) regarding the use of CCA-treated wood in places where water is almost stagnant, bioassay evaluation of treatment methods may assist in minimizing impacts of this essential protection for a useful and renewable construction material.

ACKNOWLEDGMENTS

This work was undertaken with the financial support of the Marine Science and Technology program (MAST-III) of the European Union, under contract MAS2-CT94-0100. AP was funded by the European Union Social Fund. Her work was undertaken while studying for an MSc in Shellfish Biology at the School of Ocean Sciences, University of Wales, Bangor. We thank: B. Plunkett and M. Wells at the School of Pharmacy and Biomedical Sciences, University of Portsmouth, for analyses of the leachates; P. English of Emu Environmental for assistance with conducting fertilizations; Seasalter Hatcheries (Cumbria) and P. Goulletquer of IFREMER for providing larvae; Brian Matthews of the Forest Products Research Centre, Buckinghamshire Chilterns University College for treating the test blocks; A. R. Beaumont and R. A. Eaton for constructive criticism of the manuscript.

STABLE ISOTOPE PROFILES OF *SERRIPES GROENLANDICUS* SHELLS. II. OCCURRENCE IN ALASKAN COASTAL WATER IN SOUTH ST. LAWRENCE ISLAND, NORTHERN BERING SEA

BOO-KEUN KHIM

Polar Sciences Laboratory, Korea Ocean Research and Development Institute, P.O. Box 29, Ansan 425-600, Korea

ABSTRACT Three bivalve shells (*Serripes groenlandicus*, Greenland cockle), collected alive in the south of St. Lawrence Island, have been analyzed for the stable oxygen and carbon isotopic composition using a sequential method to trace the variation of hydrographic conditions (i.e., temperature, salinity, and oxygen isotope) of ambient seawater during the life-spans of these organisms. The $\delta^{18}O$ profiles of three shells exhibit a cyclic pattern interpreted as seasonal variation of Bering Shelf Water, which is the dominant water mass at the collection site. Discernible and distinct light $\delta^{18}O$ peaks occurred in the summer of 1991, suggesting unusual hydrographic conditions. These are attributed to the migration of Alaskan Coastal Water into the south of St. Lawrence Island during the summer. The changed oxygen isotopic compositions of seawater between 1990 and 1993 in the study area supports the idea that the flow of Alaskan Coastal Water, intensified by the enhanced freshwater discharges from the Alaskan coast, can be migrated westward into the south of St. Lawrence Island. The $\delta^{13}C$ profiles also show apparent cyclicity, reflecting the variation of available carbon isotopes in relation to photosynthesis and oxidation of organic matter. A seasonal bloom of phytoplankton and consequent oxidation of organic matter is the possible cause of the noticeably light $\delta^{13}C$ peak in 1992, not the influx of terrestrial carbon or metabolically derived carbon. The warm Alaskan Coastal Water, characterized by low oxygen isotopic composition, is clearly recorded in the shell isotope profiles, which provides a record of the hydrographic variation of the ambient seawater.

KEY WORDS: *Serripes groenlandicus*, bivalve, stable isotope, water mass

INTRODUCTION

Little attention has been paid to the stable isotopic composition of shallow marine biogenic carbonates, mainly because the extreme spatial and temporal changes of hydrographic conditions make their interpretation of compositions difficult. In contrast, exceptions are the stable isotope studies on the growth rate and longevity of mollusk shells to obtain the information on population dynamics (e.g., Tanabe 1988, Jones and Quitmyer 1996). Shells of marine bivalves, gastropods, corals, and brachiopods in the nearshore and continental-shelf environment have been the object of a number of stable isotope studies because their skeleton chemistry has the potential to record the ambient seawater conditions (summarized in Rhoads and Lutz 1980). In particular, many investigations have explored the relationship between the stable oxygen and carbon isotopic compositions of bivalve shell carbonates and environmental information using microsampling to highlight high-resolution temporal changes of ambient seawater during the lifespans of living or fossil organisms (Krantz et al. 1987, Krantz 1990, Cornu et al. 1993, Weidman et al. 1994, Jones and Allmon 1995, Klein et al. 1996, Bemis and Geary 1996, Bice et al. 1996, Kirby et al. 1998, Khim et al. 2000, Khim 2001).

The hydrographic conditions in the shallow marine environment of temperate and sub-arctic regimes vary seasonally. In winter, the water column is vertically homogeneous due to mixing resulting from the convective cooling and severe wind. On the other hand, in summer, incoming freshwater discharge and heating of the surface water result in the vertical stratification of water masses in these shallow waters. For example, in the northern Bering Sea (Fig. 1), stratification develops particularly during the summer after the sea ice melts (Coachman et al. 1975, Muench et al. 1981, Coachman and Shigaev 1992, Schumacher and Kendall 1995). The migration of water mass is of great importance because the transport and dispersal of pollutants is controlled by the coastal current in the shallow marine environment. In addition, the resultant mixing of water masses plays a potential role in influencing primary productivity by reintroducing the limited nutrients (Walsh et al. 1989).

In this paper, three living bivalve (*Serripes groenlandicus*) shells were collected in the northern Bering Sea by dredging in June 1993 during the Helix 171 research cruise. From the patterns of stable oxygen- and carbon-isotope profiles, constructed using the high-resolution sequential sampling, interesting hydrographic events can be identified distinctly.

HYDROGRAPHY AND SAMPLING SITE

The northern Bering Sea is characterized by one of the largest continental-shelf seas in the world ocean (Fig. 1a). This sea, which is the connection between the North Pacific and the Arctic Ocean, is deepening slightly toward the Bering Strait. In the northern Bering Sea lie two straits, the Anadyr and Shpanberg straits, on either side of St. Lawrence Island (Fig. 1b). Northward flows through the Bering Strait (Fig. 1a; Coachman et al. 1975, Walsh et al. 1989) result from sea-level sloping toward the Arctic Ocean (Stigebrandt 1984).

Three water masses (Anadyr Water, Bering Shelf Water, and Alaskan Coastal Water) defined by their temperature-salinity profiles have been observed in the northern Bering shelf (Fig. 1b; Coachman et al. 1975). The water masses are also characterized by the unique $\delta^{18}O_w$ (i.e., $\delta^{18}O_{seawater}$ vs. V-SMOW) values (Grebmeier et al. 1990, Cooper et al. 1997). Their results showed that the separation of Alaskan Coastal Water from Bering Shelf Water was defined by $\delta^{18}O_w$ value of about −2.0 ‰. These water masses are oriented in an east-west direction across the shelf. The most saline and coldest Anadyr Water occupies the western part of Anadyr Strait, whereas the least saline and warmest Alaskan Coastal Water occurs in the eastern part of the Shpanberg Strait. Between these lies the Bering Shelf Water of intermediate temperature and salinity. The relatively strong hydrographic boundary between Anadyr Water and Bering Shelf Water is maintained during the year, but the corresponding front between Bering Shelf Water and Alaskan

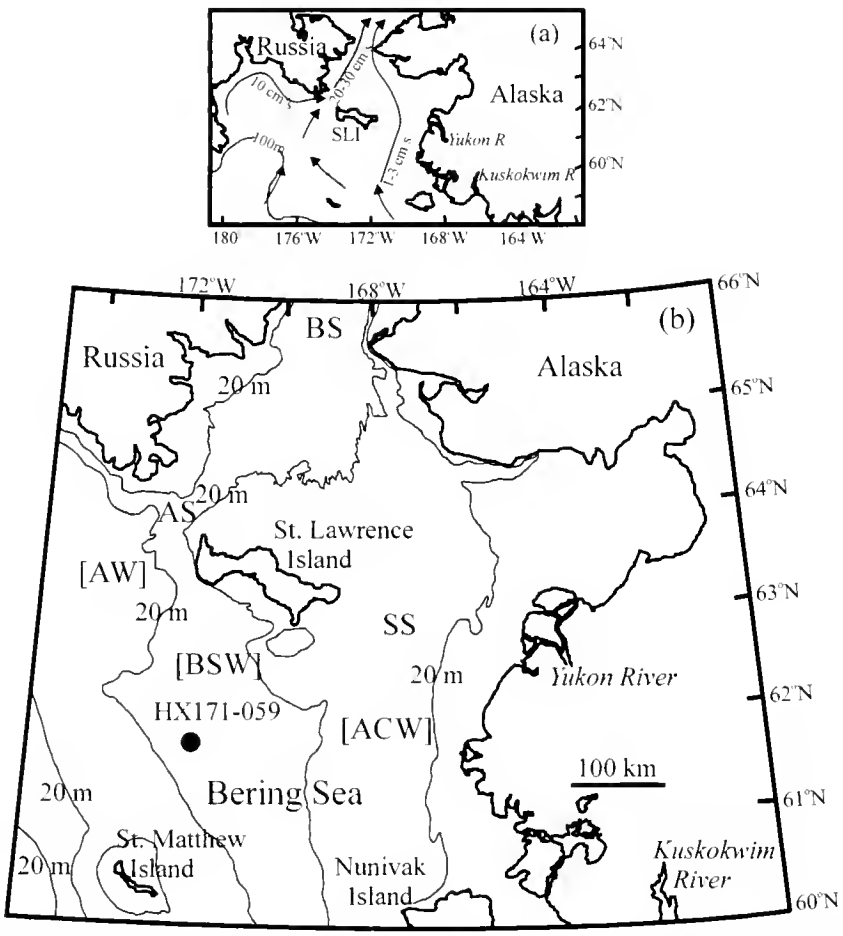

Figure 1. (a) The schematic flow pattern in the northern Bering Sea (after Schumacher and Kendall 1995). SLI: St Lawrence Island. (b) The bathymetry of northern Bering Shelf and location of sampling site (HX171-059). The three principal water masses (AW: Anadyr Water, BSW: Bering Shelf Water, ACW: Alaskan Coastal Water) are aligned in the east-west direction across the shelf. BS: Bering Strait, AS: Anadyr Strait, SS: Shpanberg Strait.

Coastal Water is usually indistinct and gradational and the lateral mixing is quite possible (Coachman and Shigaev 1992). Enhanced freshwater runoff to intensify the Alaskan Coastal Water, as well as mixing process from wind and tidal shear, works the water mass to extend its way across a front into the shelf area.

The warmer Alaskan Coastal Water (summertime bottom-water temperature: about 6°C) is characterized by a mixture of freshwater runoff with relatively saline coastal waters (Coachman 1986, Schumacher and Kendall 1995). The relatively low salinities (generally <31.8 psu, practical salinity unit) near the Shpanberg Strait are reinforced annually by the addition of Yukon River water. This marked seasonal difference in freshwater runoff causes the intensification of Alaskan Coastal Water during the warm season. Alaskan Coastal Water also shows the inter-annual variations of salinities which are the same magnitude as those of the seasonal cycle (about 0.5 psu; Coachman and Shigaev 1992).

The vertical profiles of temperature and salinity measured at the station HX171-059 (61°46.0′N, 171°16.0′W, Fig. 1b) where the bivalve shells were collected are shown in Figure 2. The water column formed a distinct two-layered stratification at the time of shell collection. High-temperature (~6.0°C) and less saline (~30.7 psu) waters form the upper layer whereas low-temperature (~0.4°C) and more saline (~31.6 psu) waters form the lower layer. A sharp thermocline lies a little deeper than the halocline, both of which maintain the water-column stability. The high temperature and low salinity of the upper layer is probably due to effects of solar radiation, and freshwater runoff and sea-ice melts, although the collection time (late June) was close to the beginning of summer when it is fairly drier. Approximately −2.0 ‰ (V-SMOW) of bottom water at the depth of 45 m is measured, which seems to be quite low, on the basis of the $\delta^{18}O_w$ definition of Bering Shelf Water (Grebmeier et al. 1990).

MATERIALS AND METHODS

Three bivalves, *Serripes groenlandicus* (Greenland cockle), were collected alive near the hydrocasting station HX171-059 (45 m deep) south of St. Lawrence Island, northern Bering Sea by dredge in late June, 1993 (Fig. 1b). This infaunal and suspended feeder is cosmopolitan in arctic and boreal regions from the subtidal zone to about 100 m. The shell of this species is composed entirely of aragonite and grows up to 10 cm as a ten-year-old adult (Andrews 1972). These features and previous research (Khim et al. 2001, submitted) suggest that *S. groenlandicus* would be useful for assessing seasonal and inter-annual hydrographic variability of the Alaskan Coastal Water from shell isotope profiles.

The growth patterns of bivalve shells with their repeated formations of annual increments provide information determining age

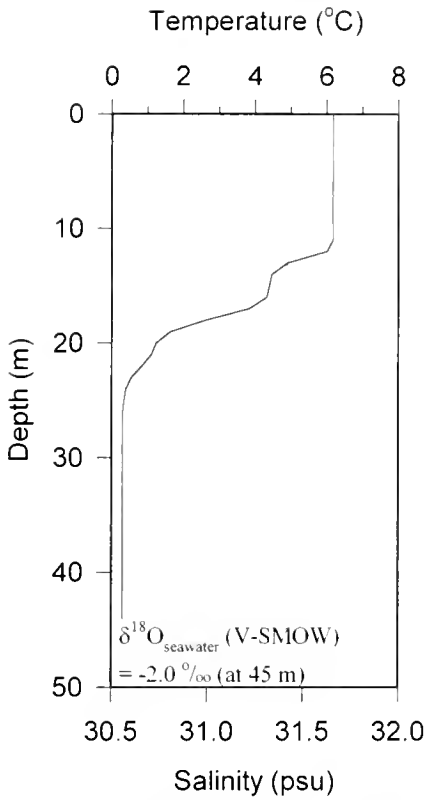

Figure 2. Vertical profiles of temperature and salinity measured at the station of HX171-059. The two-layered stratified water-column is clearly maintained by the strong thermocline and halocline that lie between 10 and 20 m. The $\delta^{18}O_w$ of bottom water (water depth of 45 m) is about −2.0 ‰ (V-SMOW) (Cooper unpubl.).

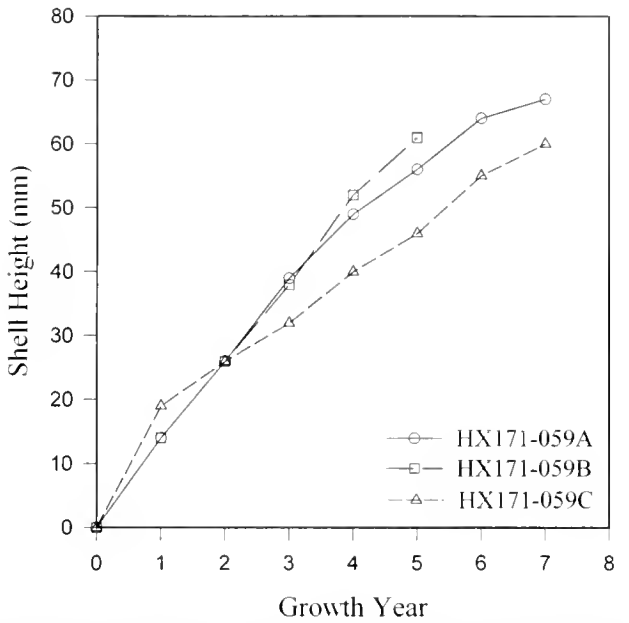

Figure 3. Growth rate of *S. groenlandicus* estimated by measuring shell height, based on the annual increments. The three shells show their different growth rate in spite of living in adjacent habitats.

and growth rates of marine bivalves (Rhoads and Lutz 1980, Jones and Quitmyer 1996). The bivalve *S. groenlandicus* produces annual growth marks which are correlated to its isotopic record (Khim et al. 2001). Figure 3 shows the growth rate history of analyzed shells using growth marks. Since the shell specimens were collected alive in 1993, calendar years may be related to the sampling intervals by counting growth bands backward from the shell margin. Consecutive sampling for isotopic determinations of shells is schematically shown in Figure 4. No sampling was done near the umbo (younger ages) because of the thin outer shell layer and near the shell margin (older years) because of the very slow growth rate.

Preparation technique for stable isotopic analyses was taken from Krantz et al. (1987). The specimens were soaked in a 5% sodium hypochlorite solution and rinsed in distilled deionized water to remove the organic matter from the shell exterior. One valve of the mollusk specimen was radically cut along the axis of maximum growth. A serial shell-sampling technique produced a set of individual carbonate powders (approximately 2 mg), which were collected in ontogenetic sequence from the outer shell layer with a 0.3-mm dental drill bur. Care was taken to avoid the penetration of the inner nacreous layer since these boreal bivalves have a thin outer layer. Isotope measurements were carried out at the University of Maine. The number of samples obtained from the specimens (HX171A, HX171B, and HX171C) are twenty, twenty-three, and twenty, respectively (Fig. 4).

Stable oxygen and carbon isotopic ratios were determined using an on-line, automatic carbonate preparation device attached to a VG Isogas PRISM isotope ratio mass spectrometer. The evolved CO_2 gas was measured after reaction in 100% phosphoric acid at 90°C. All isotope values are reported in the standard δ notation of per mil (‰) unit as the ratio of $^{18}O/^{16}O$ or $^{13}C/^{12}C$ in the sample relative to a V-PDB reference (Craig 1957, Coplen 1994). Analytical precision based on NBS-19 carbonate powders yield better than ±0.10‰ for $\delta^{18}O$ and ±0.07‰ for $\delta^{13}C$.

RESULTS AND DISCUSSION

Stable oxygen- and carbon-isotope profiles of three shell specimens are illustrated in Figure 5. The vertical axis is inverted to show the low $\delta^{18}O$ values toward the top, and the horizontal axis shows the ontogenetic growth of shell from left to right. In general, based on the thermodynamic behaviors of the oxygen isotopes in the skeletal formation (Urey 1947, Epstein et al. 1953, Grossman and Ku 1986), the low $\delta^{18}O$ values of the oxygen-isotope profile reflect the high seawater temperature during summer whereas the high values represent the low temperature during winter. Isotope values for sampled years of each shell are summarized in Table 1.

All the oxygen-isotope profiles are clearly cyclic and seasonal, but their patterns are different among the shells in the same year (Fig. 5). It may be due to the different growth rate, as judged from the width of annual bands (Fig. 3). The specimen HX171A shows a fairly low amplitude of seasonal $\delta^{18}O$ variation (Fig. 5a), ranging from 0.45 to 1.22‰ (Table 1). The calculated seasonal temperature variations through simple temperature fractionation of oxygen isotopes (−0.23/°C, O'Neil et al. 1969) are about 2 to 5°C, which corresponds to the temperature of the Bering Shelf Water (Coachman et al. 1975). The shell HX171B has a small $\delta^{18}O$ variation (about 0.8 ‰) in 1990 similar to those of HX171A (Fig. 5b), but has a prominent signal of the lowest $\delta^{18}O$ value in the summer of 1991, the amplitude of which is up to about 2.2 ‰ (Table 1). For the same years, the pattern and amplitude of the profile of specimen HX171C are similar to those of HX171B with an amplitude

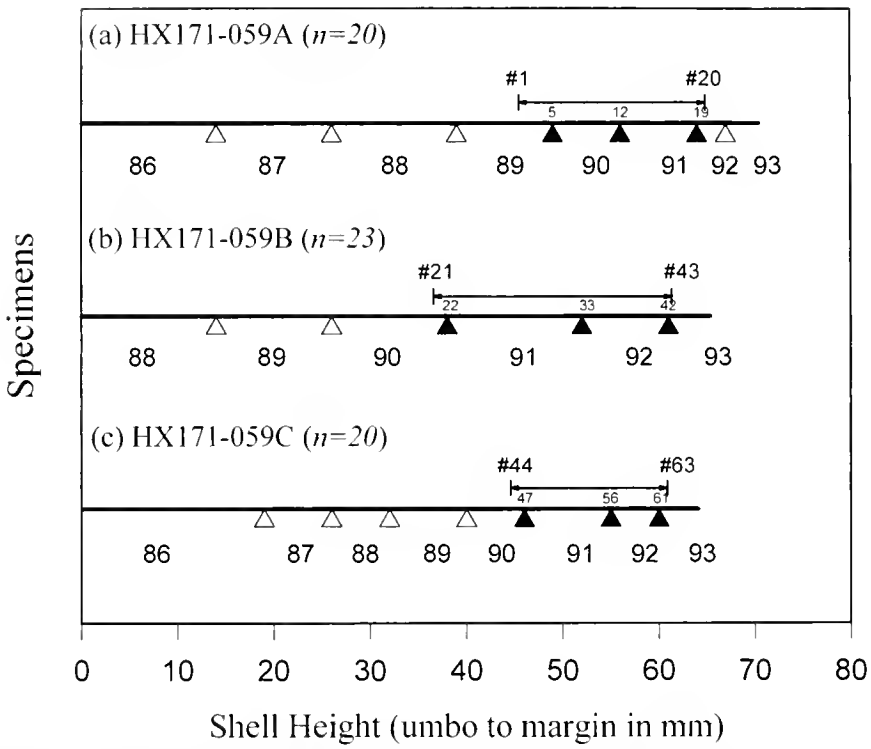

Figure 4. Sampling scheme for obtaining carbonate powders by drilling along the shell growth. The identification of annual bands along with the backward counting from margin provides the matching year for the individual isotope profile.

of 1.6‰ (Fig. 5c). Thus, the most remarkable feature of the oxygen-isotope profiles is the event in the summer of 1991 that marks the lightest $\delta^{18}O$ value obtained. A similar pattern in the oxygen-isotope profiles interpreted due to changes of hydrographic properties has been reported in mid-Atlantic coastal shells (Krantz et al. 1987). The lack of a distinct peak in the summer of 1991 for specimen HX171A is problematic. However, the most plausible explanation is that this shell lived far from the area where the two specimens (HX171B and HX171C) were obtained because the trawling area for collection was too large.

In terms of the seasonality of the $\delta^{18}O$ profiles, the bivalves can record the seasonal temperature variations during their life-spans through the isotopic fractionation of shell carbonate, under the assumption that the oxygen isotope values of ambient seawater are uniform. A variety of previous investigations substantiated that the $\delta^{18}O$ variations are controlled primarily by seasonal changes of seawater temperatures (Cornu et al. 1993, Bemis and Geary 1996, Khim et al. 2000), although the bivalve shell imperfectly records the lowest temperature due to either the growth cessation or slow growth rate during the winter (Krantz et al. 1987, Weidman et al. 1994). The $\delta^{18}O$ variation of HX171B in 1991 (about 2.2 ‰) corresponds to a seasonal temperature change of seawater of approximately 9°C, based on temperature fractionation (O'Neil et al., 1969). This seasonal temperature range is larger than expected when compared to the present-day hydrographic conditions occupied by the Bering Shelf Water (Coachman et al. 1975, Coachman and Shigaev 1992) as well as to the seasonal variations expected from HX171A (Fig. 3). Thus, at a first approximation, such seasonal temperature change in 1991 calculated from the amplitude of oxygen-isotope profile for HX171B is unlikely to occur. The large part of variation may be due to another factor to affect oxygen isotopic composition of shell carbonate when organisms lived.

An alternative plausible and potential variable to influence the oxygen isotopic composition of shell carbonates is the oxygen isotopic composition of seawater ($\delta^{18}O_w$) itself (Epstein et al. 1953, Grossman and Ku 1986). In general, the $\delta^{18}O_w$ values are linearly correlated with the salinity (Craig and Gordon 1965); the high-salinity water mass is characterized by the high $\delta^{18}O_w$ value and *vice versa*. In the northern Bering Shelf region, the Alaskan Coastal Water has lower $\delta^{18}O_w$ values than the Bering Shelf Water (Grebmeier et al. 1990, Cooper et al. 1997, Cooper unpubl.). Figure 6 illustrates the temporal variation of bottom water $\delta^{18}O_w$ values in the southern part of St. Lawrence Island. In June, 1990, the $\delta^{18}O_w$ variations demonstrate that the water masses are aligned in east-west direction and $\delta^{18}O_w$ values increase gradually westward (Fig. 6a, Grebmeier et al. 1990). Where the shells were collected in June, 1993, the increasing $\delta^{18}O_w$ trend can be similarly observed in the south of St. Lawrence Island (Fig. 6b, Cooper unpubl.). However, the absolute $\delta^{18}O_w$ values in 1993 became much lower by as much as approximately 0.5 ‰ than those in 1990. Such low $\delta^{18}O_w$ values in 1993 are attributed to the migration of Alaskan Coastal Water into this area, resulting in the drop of $\delta^{18}O_w$ value. Therefore, although $\delta^{18}O_w$ data in 1991 are unavailable in the present study, the distinct pattern of oxygen-isotope profiles demonstrates that the lightest $\delta^{18}O$ peak occurred in 1991 is presumably caused to much extent by the low $\delta^{18}O_w$ value of Alaskan Coastal Water. Krantz et al. (1987) also showed that short-term low-salinity events in the mid-Atlantic coastal area can be identified from the pattern of oxygen-isotope profiles.

The carbon-isotope profiles of live shells also show periodic patterns similar to oxygen-isotope profiles (Fig. 5). In general, the high $\delta^{13}C$ values are observed during mostly the entire season, whereas the low $\delta^{13}C$ values occur along with the low $\delta^{18}O$ values that reflect the warm season. The $\delta^{13}C$ profile of specimen

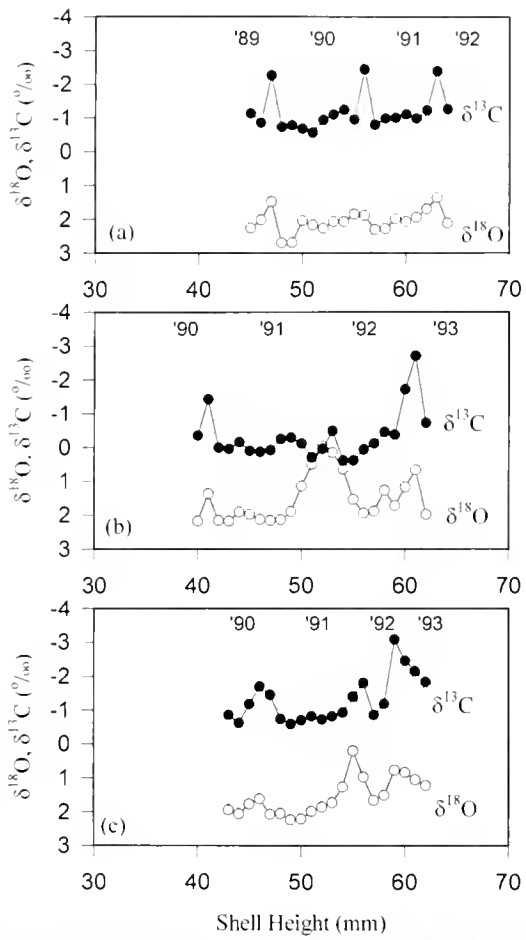

Figure 5. Stable oxygen- and carbon-isotope profiles of living bivalve *S. groenlandicus*. (a) HX171A, (b) HX171B, (c) HX171C. Note the low $\delta^{18}O$peaks in 1991 of HX171B and HX171C and the low $\delta^{13}C$ values that occurred in 1992 in HX171B and HX171C.

HX171A is cyclical with almost consistent amplitudes over the sampled interval (Fig. 5a). The mean $\delta^{13}C$ and range of variation are about −1.18 ‰ and 1.70 ‰, respectively (Table 1). The mean $\delta^{13}C$ values of HX171B and HX171C are −0.33 and −1.24 ‰, respectively, the latter of which is close to that of HX171A. The enriched $\delta^{13}C$ values of HX171B may be mainly due to the different $\delta^{13}C$ of seawater dissolved inorganic carbon (DIC) as a background level, although these shells were dredged in a same locality. The $\delta^{13}C$ patterns of HX171B and HX171C are similar in spite of different growth rates, but clearly distinguishable from that of HX171A (Fig. 5). In 1992, the light $\delta^{13}C$ peak is observed distinctly in both HX171B and HX171C, as similar event of oxygen-isotope profile in 1991. The approximate amplitude is up to 2.8 ‰ (Table 1). In addition, the shapes of oxygen- and carbon-isotope profiles of these two shells are alike in both 1992 and 1993.

Several probable variables affecting the carbon isotopic composition of shell carbonates are as follows: $\delta^{13}C$ of the DIC reservoir associated with phytoplankton productivity and reoxidation of organic matter, effects of temperature on ^{13}C fractionation, and seasonal physiological effects related to metabolic activity (Rubinson and Clayton 1969, Emrich et al. 1970, Tanaka et al. 1986, Rosenberg and Hughes 1991, Wefer and Berger 1991, Romanek et al. 1992, Klein et al. 1996). A primary factor is the available ^{13}C atoms in ambient seawater DIC (Mook and Vogel 1968), but other variables can be important. In particular, seasonal variations of the $\delta^{13}C$ values of the shell isotope profiles documented in the previous studies have been explained as a result of modification in the level of $\delta^{13}C$ of seawater DIC (Krantz et al. 1987). Due to the phytoplankton role in fractionating carbon isotopes during photosynthesis producing organic matter, the heavy carbon atoms are easily incorporated into the shell carbonate. On the other hand, isotopic fractionation through the decomposition of organic matter causes the light carbon isotopes to be assimilated in the shell carbonate (Kroopnick 1980).

The low $\delta^{13}C$ values of HX171A in summer may reflect seasonal phytoplankton productivity and decomposition of organic matter at the bottom. In the northern Bering Sea, the seasonal bloom of phytoplankton occurs during the warm months when the sea ice is retreating and the influx of nutrient-rich water is increasing (Hansell et al. 1993, Springer and McRoy 1993). In the Alaskan Coastal Water, the blooming duration may not be apparently long enough to produce a distinguishing signal in the ^{12}C atoms (Walsh et al. 1989, Coachman and Shigaev 1992). Alternatively, there is a possibility that the light $\delta^{13}C$ peaks may reflect the inclusion of metabolic light carbon formed by growing much faster during warm, favorable conditions (Rosenberg and Hughes 1991, Wefer and Berger 1991). In spite of lacking evidence to demon-

TABLE 1.

Summary of minimum, maximum and variation of stable oxygen and carbon isotope judged by the individual year over the sampled intervals.

		$\delta^{18}O$			$\delta^{13}C$

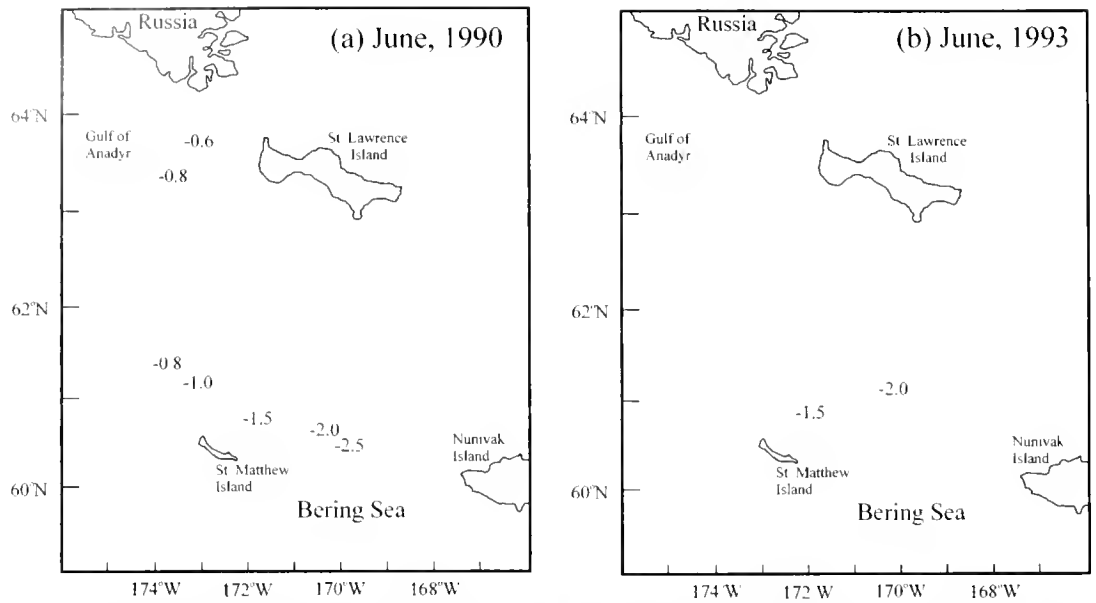

Figure 6. The spatial distribution of $\delta^{18}O_w$ values in the south of St. Lawrence Island. (a) June 1999 (from Grebmeier et al. 1990), (b) June 1993 (from Cooper unpubl.). The absolute $\delta^{18}O_w$ values in 1993 are greater by as much as approximately 0.5 ‰ compared to those in 1990. Such low $\delta^{18}O_w$ values in 1993 may be due to the migration of Alaskan Coastal Water into this area, resulting in the drop of $\delta^{18}O_w$ values.

strate that the terrestrial carbon species transported by Alaskan Coastal Water (Naidu et al. 1993), the light terrestrial carbon should be considered to interpret. Terrestrial carbon from river discharge is prominently supplied during the warm season by the intensified Alaskan Coastal Water. If the low $\delta^{18}O$ peaks observed during the summer of 1991 result from the influx of Alaskan Coastal Water, then the water mass maintains plenty of ^{16}O atoms along with low salinity caused by increasing river runoff. However, the $\delta^{13}C$ profile in that year does not show the corresponding low peaks. Thus, the addition of light terrestrial carbon during the warm season is unlikely to cause the low peak.

The distinct low $\delta^{13}C$ peak of 1992 is informative because the $\delta^{18}O$ profile has no equivalent peak in the same year (Fig. 5). As explained above, such light peak is not attributable to light carbon of terrestrial origin transported by riverine discharge. The $\delta^{13}C$ minimum in 1992 can be identified in both HX171B and HX171C, but not in HX171A. It is difficult to judge which process causes this discernible low $\delta^{13}C$ peak. The plausible mechanism resulting in this $\delta^{13}C$ peak is the abrupt change of $\delta^{13}C$ of seawater DIC by the oxidation of organic matter generated from phytoplankton blooms. A stratified water-column, a short duration of primary production on the surface layer, and a fairly shallow depth are all conditions likely to change the $\delta^{13}C$ of bottom water. Thus, the light carbon is assimilated easily in the formation of shell carbonate.

ACKNOWLEDGMENTS

This study was done during a stay at the University of Delaware. I thank Dr. Lee W. Cooper (Oak Ridge National Laboratory) for supplying the live shell specimens and unpublished seawater oxygen isotope data and Dr. David E. Krantz (now US Geological Survey) for discussing the isotope results. Dr. Doug Introne (University of Maine) is appreciated for his analyses of the stable isotopic composition of shell carbonate powders. I would also like to thank Dr. Sandra E. Shumway (editor), Dr. Louise Purton-Hilderbrand (Trinity College), and an anonymous reviewer for their critical and constructive comments and suggestions. This work was carried out through the support of the National Science Foundation (DPP-9300684 and DPP-9423663) and Ministry of Maritime Affairs and Fisheries (PN00062).

ASPECTS OF THE GONADAL CYCLE IN THE ANTARCTIC BIVALVE *LATERNULA ELLIPTICA*

G. BIGATTI,[1] P. E. PENCHASZADEH,[1]* AND G. MERCURI[2]

[1]*Facultad de Ciencias Exactas y Naturales, UBA y Museo de Ciencias Naturales–CONICET, Av. Angel Gallardo 470, Buenos Aires, Argentina;* [2]*Instituto Antártico Argentino, Cerrito 1248, 1010 Buenos Aires, Argentina*

ABSTRACT Vitellogenesis and oocyte growth in *Laternula elliptica*, a common hermaphrodite bivalve living in the soft muddy bottoms of the Antarctic continent, are reported. Formation of the gelatinous layer surrounding the oocyte, gonadic development, accumulation of mature oocytes, and spawning events were studied through histological evidence. Gonads were observed to reach maturity at a size of 49 mm. Vitellogenesis has been found to last seven months, and storage of oocytes before spawning was observed. It has been observed that once sexually mature, the animals remain with sperm cells and oocytes available during the entire year, suggesting that individuals would be prepared to spawn at any moment, probably depending on environmental conditions.

KEY WORDS: *Laternula elliptica*, Antarctic clams, vitellogenesis, oocyte growth, first maturation

INTRODUCTION

Laternula elliptica (King & Broderip 1832) is possibly the most common bivalve in the Antarctic continent wherever soft muddy bottoms are present (Powell 1965). It burrows deeply into the substrate (Stout & Shabica 1970); densities of 50 individuals per m^2 with a fresh weight biomass of 2–3 kg/m^2 have been reported (Hardy 1972).

Recently several authors have studied different aspects of the reproduction of *L. elliptica* (Pearse et al. 1986; Pearse et al. 1987; Urban & Mercuri 1998; Ansell & Harvey 1997). Several questions remain unanswered, however. This article deals with the vitellogenesis period and oocyte growth within the ovarian portion of the hermaphrodite gonad, the size and age of gonadic maturation, the formation of the gelatinous layer surrounding the oocyte, the accumulation of mature oocytes, and spawning events, studied from histological evidence.

MATERIAL AND METHODS

The material was obtained by one of the authors (G.M.) during a joint German-Argentine project (Klöser & Arntz 1995; Urban & Mercuri 1998), at the location of Potter Cove, King George Island, South Shetland Islands. A monthly sampling was conducted at a fixed station at 10 m depth (see Urban & Mercuri 1998, for locality details). Histologic slides were prepared for one complete year of sampling (1993–1994). Gonads were fixed in Bouin's solution, preserved in 70% alcohol and treated with common inclusion procedures. Sections of 5 microns were stained with Harris' hematoxylin and eosin (Merck). The ovaries of 30 individuals of standard adult bivalves (of about 65–80 mm in shell length) were studied for each monthly sample. A total number of 1113 oocytes (73–117 per monthly sample) with distinct nucleolus were measured, comprising the whole visual field.

In a later sample, in February 2000, gonads of 22 individuals of about 27–73 mm were studied with the same procedures in order to determine the size of gonadal development and maturation.

RESULTS AND DISCUSSION

Under the stereoscopic microscope it is possible to observe, in the ovarian portion of mature clams, the mature oocytes and empty spaces related to partial spawning (Figs. 1–3).

A gelatinous layer (Figs. 4–9) envelops the mature oocyte. This outer layer becomes visible (3.1 SD 1.3 microns thick) during vitellogenesis when the oocytes are 90–100 microns in diameter. Maximum thickness (13.6 SD 5.0 microns) of the gelatinous layer is reached in oocytes of 220 microns in complete diameter (these oocytes have a mean cytoplasmic diameter of 193 microns).

According to the histograms of oocyte diameter frequencies, this process of wall formation takes 3–4 months, starting in March–April and ending in September (Figs. 10 and 11). Ansell and Harvey (1997) stated that after fertilization this gelatinous envelope condensed to form a strong, sticky, elastic capsule in which further development took place. We consider this gelatinous layer to be a vitelline membrane, formed by the oocyte itself (Huebner & Anderson 1976).

The largest oocyte mean diameter we measured, including the gelatinous layer, was 220.7 microns in February 1994 (Fig. 10), but we consider the oocyte to be mature at 171.5 microns external diameter, and the mean mature oocyte is 195.2 microns (including gelatinous layer).

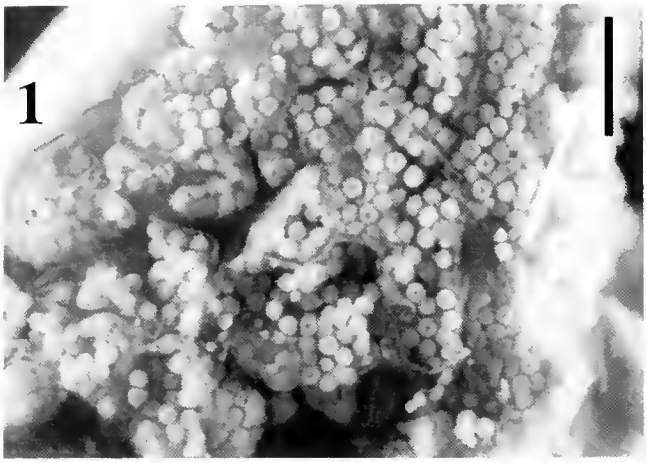

Figures 1–3. Ovarian portion of gonads of *Laternula elliptica* (>60 mm shell length) viewed through stereoscopic microscope. (1) Ripe ovary; (2) Partially spent ovary; (3) Spawned ovary with remnant oocytes. Scale Bar = 1200 microns.

The modal diameter peaks for bigger oocytes show no variation from January to July (171.5 microns). But modal diameters of the small oocytes show a remarkable constant tendency to grow from January (55.5 microns) to June (142.5 microns); this is the main period of vitellogenesis. The period of favorable light conditions to phytoplankton growth in Potter Cove appeared to be very limited, approximately 1.5 months during summer (Schloss et al. 1997). Apart from that, resuspension of benthic material and possible input of terrigenous material constitute the main carbon source in summer time, while resuspended material or secondary bacterial production would account for it during the rest of the year (Schloss et al. 1997).

We consider that, as resorption of unspawned oocytes was never observed in any case, there is currently a storage of large mature oocytes in the female follicles, ready to spawn during the entire year. Protected lecitotrophic embryos, nourished by a considerable amount of yolk reserves which enable them to avoid a free swimming larvae stage in the first phases of the development, is the reproductive mode for *L. elliptica* (Pearse et al. 1986; Bosch & Pearse 1988).

Urban and Mercuri (1998) found that ripe ovaries seem to dominate, with values between 60–80% throughout the whole year, and only during the warmest two months (February and March) spent ovaries dominated, with ripe ovaries being reduced to about 25%. The authors suggested that it is most likely that the oocyte development cycle last longer than one year. Our results conclude that the oocytes complete their growth in less than seven months, and are stored until spawn. Once sexually mature, the animals remain with sperm cells and oocytes available during the whole year, suggesting that individuals would be prepared to spawn at any moment, probably depending on environmental conditions.

In a later sample performed during February 2000 in the same study area, microscopic differentiation of both testicles and ovarian follicles was observed at a size of 27 mm. Taking into account growth rates estimated by Brey and Mackense (1997) and by Urban and Mercuri (1998), this size corresponds to individuals <2 years old. Maturity in the male portion of the gonad is evidenced by the existence of mature sperm cells at a size of 30 mm shell length (Fig. 6).

At a shell length of 32 mm, which corresponds to individuals ~3 years old, it is possible to observe some oocytes covered by the characteristic gelatinous layer (up to 140 microns in external diameter). Ovaric maturity might then be reached when the individuals attain a size of 49 mm shell length, which corresponds to an age of approximately 4 years. It is at this stage that the gelatinous layer containing oocytes of 170 microns external diameter can be observed.

We conclude then that *L. elliptica* is a simultaneous hermaphrodite, completely mature at the age of 4 years. Information is still needed about its first stages of development, in order to assess the possibility of early development of any of the gonadic portions relative to the others.

FIRST DESCRIPTION AND SURVEY OF THE EGG MASSES OF *LOLIGO GAHI* (D'ORBIGNY, 1835) AND *LOLIGO SANPAULENSIS* (BRAKONIECKI, 1984) FROM COASTAL WATERS OF PATAGONIA

PEDRO J. BARÓN

Centro Nacional Patagónico, Consejo Nacional de Investigaciones Científicas y Técnicas, Boulevard Brown s/n, Puerto Madryn (9120), Chubut, Argentina

ABSTRACT A survey was conducted on the egg masses of *Loligo gahi* (D'Orbigny, 1835), a target of an important squid fishery in the Southwest Atlantic, and *L. sanpaulensis* (Brakoniecki, 1984), a species exploited as a by-catch species in artisanal fisheries from Brazil to Argentina. The egg masses are described, and several spawning areas are identified. *L. gahi* egg masses were composed of a variable number of capsules (6–345) enclosing 40–150 eggs/embryos. *L. sanpaulensis* egg masses consisted of numerous capsules (6–465) containing approximately 240–320 eggs/embryos. The size range of the eggs was 2.1–2.3 mm for *L. gahi* and 1.2–1.3 mm for *L. sanpaulensis* from Nuevo Gulf, showing good correspondence with size of the mature oocytes carried in the oviducts by the females of each species at the same location. *L. gahi* egg masses were located in San Matías, the San José and Nuevo gulfs, Cape Tres Puntas, and Beagle Channel, usually attached to hard substrates (e.g., kelp) or objects laying on the seafloor (e.g., stones, shells, ropes, or even fishing lines) at depths from 1–15 m. *L. sanpaulensis* egg masses were found in Nuevo Gulf on sandy and muddy bottoms at depths of 5–15 m. Throughout a survey conducted from March 1996 to February 2000 in Nuevo Gulf, in an area within the distribution range of both species, *L. gahi* egg masses were found more frequently; *L. gahi* egg masses were observed every month of the year but February, whereas *L. sanpaulensis* egg masses were detected only from February to May.

KEY WORDS: *Loligo gahi, Loligo sanpaulensis*, egg masses, eggs, embryos, spawning grounds, Argentina, Patagonia

INTRODUCTION

Two loliginid squid species inhabit the Atlantic coast of Patagonia: *Loligo gahi* (D'Orbigny, 1835) and *L. sanpaulensis* (Brakoniecki, 1984). *L. gahi* is a species distributed in the southeastern Pacific from Perú to Tierra del Fuego (Cardoso et al. 1998) and in the southwestern Atlantic from Tierra del Fuego to 36°S (Castellanos & Cazzaniga 1979, Vigliano 1985). *L. sanpaulensis* is a species associated with coastal waters, distributed from San Jorge Gulf (Castellanos 1967) to Brazil (20°S) (Roper et al. 1984). Both species are present in the San Matías Gulf (Gonzalez 1999) and in the Nuevo and San Jose gulfs (Ré et al., unpublished manuscript). The fishery of *L. gahi* in the southwestern Atlantic is the second most important loliginid fishery worldwide, reaching average annual captures over 56,000 t during 1988–1997 (FAO 1999). *L. sanpaulensis* constitutes a by-catch species for local fisheries along the Atlantic coast of South America from 23°S (Costa & Fernandes 1993) to 43°S (Castellanos & Cazzaniga 1979).

The spawning areas of loliginid squids have been studied in some commercially valuable species (Vecchione 1988, Augustyn 1990, Baddyr 1991, Porteiro & Martins 1992, Sauer et al. 1992, Sauer et al. 1993). The data on the spawning areas of loliginids in the southwestern Atlantic are scarce (Andriguetto & Haimovici 1996, Ré et al., unpublished manuscript, Arkhipkin et al., 2000). Moreover, the location of these areas has been a matter of speculation until recently (Chesheva 1990, Hatfield et al. 1990, Andriguetto & Haimovici 1996).

The egg masses of Loligo are typical among those of the cephalopods (Arnold & Williams Arnold 1977, Sweeney et al. 1992); however, there are aspects (e.g., the number of capsules per egg mass, the number of eggs per capsule, the egg sizes, and the type of substratum on which the egg masses are attached) that are important to characterize the egg masses to the taxonomic level of species and that have not been reported in *L. sanpaulensis* and have been studied only recently in *L. gahi* (Guerra et al. 2001, Arkhipkin et al. 2000). For both species, the existence of one or more laying periods at different locations is still a subject of debate (Hatfield et al. 1990, Hatfield 1991, Costa & Fernandes 1993, Andriguetto & Haimovici 1996). The aims of the present study were (1) to find and identify the egg masses of *L. gahi* and *L. sanpaulensis*, (2) to locate spawning areas of both species along the Atlantic coast of Patagonia, (3) to study the seasonality of both species' spawning in a given area, and (4) to relate seasonality to the local temperature regime to identify critical values of temperature that could restrict or favor spawning.

MATERIALS AND METHODS

A continuous survey on the egg masses deposited by female loliginid squids in Nuevo Gulf, Argentine Patagonia (Fig. 1), was conducted between March 1996 and June 1998. Four buoyed ropes with weights attached were deployed on the sea bottom at Ameghino Point (March 1996-June 1996) and Kaiser Beach (July 1996-June 1998) (Fig. 1) at depths from 5–15 m (200—1,000 m from the coast). To stimulate *Loligo* females to lay their eggs on the ropes, artificial egg masses made up of small polyethylene bags filled with polystyrene spheres were attached to the ropes' bottom ends. The ropes were monitored every 2–4 wk depending on weather conditions. Seawater temperature, salinity, and pH were registered with a manual electronic sensor (Horiba Inc., Kyoto, Japan) at every control date. From August 1996 to February 2000, eight other spawning sites were found at Nuevo and San José gulfs and Beagle Channel (Fig. 1) by scuba diving and by collection of stranded egg masses on the beach. Additionally, two Loligo spawning sites were identified at Cape Tres Puntas and San Matías Gulf (Fig. 1) from the analysis of egg masses provided by Dr. Alejandro Petovello (Santa Cruz Province Fisheries Department) and Dr. Raúl Gonzalez (Almirante Storni Marine Biology Institute).

The capsules from each egg mass were counted, and the average number of eggs/embryos per capsule was estimated from a 10-capsule sample per egg mass or from the capsules available when less than 10. The embryonic stages present in each egg mass

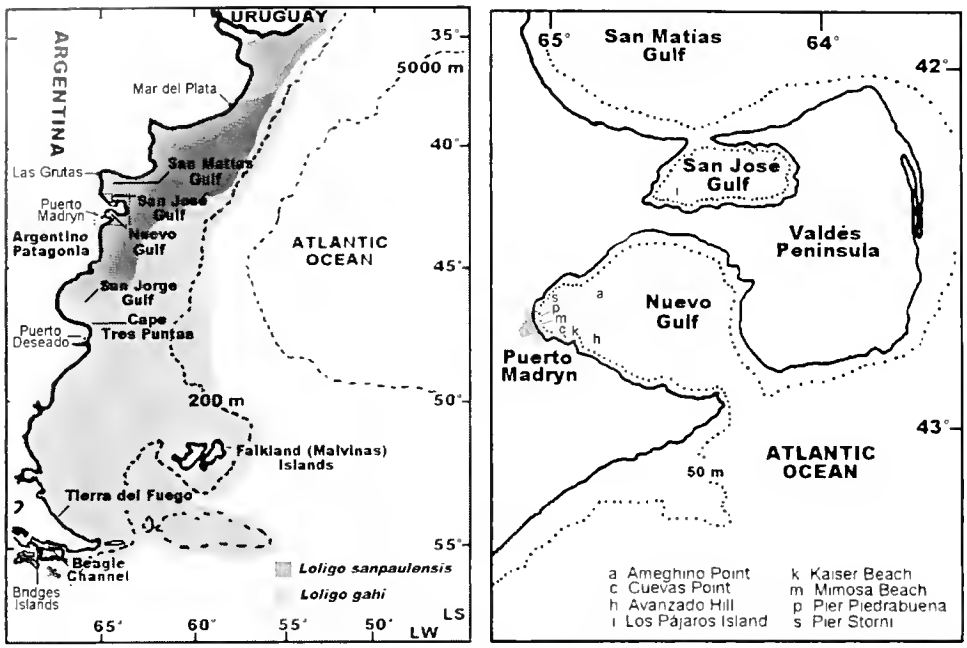

Figure 1. Area of distribution of *Loligo gahi* and *L. sanpaulensis* in Patagonia and location of the spawning areas identified in this study. Data from Vigliano (1985), Inada et al. (1986), and personal observations.

were identified following Arnold's scale (Arnold 1965). A 100-egg sample per egg mass (10 eggs × 10 capsules) was measured in egg masses showing embryonic stages previous or equal to 13 (beginning of the blastoderm expansion; Arnold 1965). On the basis of the egg counts and measurements, the egg masses were classified into different types. To identify these egg mass types to the species level, samples of the mature oocytes were taken from the ovaries and oviducts of 10 *L. gahi* (89–192 mm ML) and 10 *L. sanpaulensis* (67–157 mm ML) mature females captured by coastal seine and jigging at Nuevo Gulf. For each species, the lengths of 200 oocytes (20 oocytes × 10 females) were measured. Additionally, samples of 100 eggs/mature oocytes were randomly taken in triplicate from each of the egg mass types and from the ovaries and oviducts of the *L. gahi* and *L. sanpaulensis* mature females (3 × 10 oocytes × 10 females) from Nuevo Gulf, dried to constant weight, and weighed. All measurements were done at 25× magnification with a Wild dissecting microscope (Wild, Heerbrugg, Switzerland) equipped with an eyepiece; weights were taken to the nearest 0.01 g using a Mettler PC 440 – Delta Range electronic scale (Mettler Instruments, Zürich, Switzerland). The hatching paralarvae from each egg mass type were characterized on the basis of their mantle lengths and chromatophore arrangements.

RESULTS

Two egg mass types with distinctive eggs/embryos sizes and numbers of eggs per capsule were found in Nuevo Gulf. Each egg mass type, and also the capsules, eggs, and embryos themselves, will be hereafter referred to as type 1 and 2. The type 1 Loligo egg masses were regularly found attached to the ropes at the two locations of the same gulf where they were deployed: Ameghino Point and Kaiser Beach (Fig. 1; Table 1). They were also located by scuba diving on gravel substrate or on objects such as shells, ropes, or fishing lines at different locations of the same gulf: Pier Piedrabuena (Puerto Madryn), Cuevas Point, Avanzado Hill, and by collection of stranded material on Mimosa Beach (Fig. 1; Table 1). Type 1 egg masses were also found throughout a wide latitudinal range along the Atlantic coast of Patagonia: Las Grutas (San Matías Gulf), Los Pájaros Island (San José Gulf), Puerto Deseado (Cape Tres Puntas), and Bridges Islands (Beagle Channel). Type 2 egg masses were found only by scuba diving, anchored in sandy or muddy bottoms of Nuevo Gulf, near the pillars of Pier Almirante Storni (Puerto Madryn), and in the vicinity of Las Piedras Park, a recreational diving spot located a few hundred meters from the Puerto Madryn's waterfront (Fig. 1; Table 1).

Type 1 and 2 egg masses are well-defined structures and are made up of several capsules attached to each other and to the substrata at their basal ends by short stalks. Each capsule consists of an inner core of jelly surrounded by a spiral band of jelly that contains a row of eggs and an external covering formed by several layers of translucent material that provides cohesion and protection to the eggs (Fig. 2). The bases of the stalks, composed of the same material as the capsule's core and deprived of any external layer, are entangled, forming a bundle that is attached to the substrate. The number of capsules per egg mass varied from less than 10 to more than 300 for the type 1 egg masses and from less than 10 to more than 400 for the type 2 egg masses (Table 1). Some of the egg masses found during the survey consisted of groups of capsules, each one containing embryos in a particular stage of development (multiple egg masses; Table 1). This can be attributed to the deposition of egg capsules in a common egg mass by more than one female at various time intervals. The average number of eggs/embryos per capsule was 69 (n = 340) for the type 1 and 298 (n = 50) for the type 2 egg masses, but these numbers varied considerably between egg masses of the same type (Table 1).

Both type 1 and 2 eggs were approximately oval in shape, with the animal pole more pointed than the vegetal pole. The average size of the eggs was 2.2 mm (2.1–2.3 mm; n = 500) for type 1 egg masses and 1.2 mm (1.2–1.3 mm; n = 200) for type 2 egg masses (Fig. 2). The dry weights of 100 eggs were 0.10 g for each of the three replicates of type 1 eggs and 0.03 g for each of the three replicates of type 2 eggs.

No egg masses were found on the ropes on 8/13/96, 1/18/97, 2/17/97, and 4/23/97. Embryonic stages follows the scale of Arnold (1965).
n/a: not available.
*Multiple egg mass (groups of capsules with embryos at different stages of development).

Besides larger absolute sizes, type 1 embryos show external yolk sacs proportionally larger than those of type 2 embryos at the same stages of development (Fig. 3). Therefore, throughout their development, type 1 embryos show features closer to those described by Naef (1928) for the embryos of *L. vulgaris* (Lamark, 1798), and type 2 embryos show characteristics that resemble those illustrated by Arnold (1965) for the embryos of *L. pealei* (Le Sueur, 1821). At hatching, type 1 embryos attain mantle lengths of 2.6–3.2 mm, and type 2 embryos attain mantle lengths of 1.4–1.7 mm (Fig. 3). The most common chromatophore arrangements found on the embryos of both types of paralarvae are shown in Figure 4. Chromatophores were red or yellow on the ventral surface of both types of paralarvae, brown or yellow on the dorsal surface of type 1 paralarvae, and only yellow on the dorsal surface of the type 2 paralarvae. Orange chromatophores were observed only on the embryos in stages 26–28 of Arnold's scale (Arnold 1965). The cheek patches of the type 1 hatchlings consisted in four red chromatophores, but three chromatophores on either one or both cheeks were frequently observed. The type 2 hatching paralarvae displayed only two red chromatophores on each cheek patch.

The average size of the mature oocytes sampled from the ovaries and oviducts of 10 *L. gahi* females was 2.2 mm (2.0–2.4 mm; $n = 200$); the average size of the oocytes sampled from 10 female

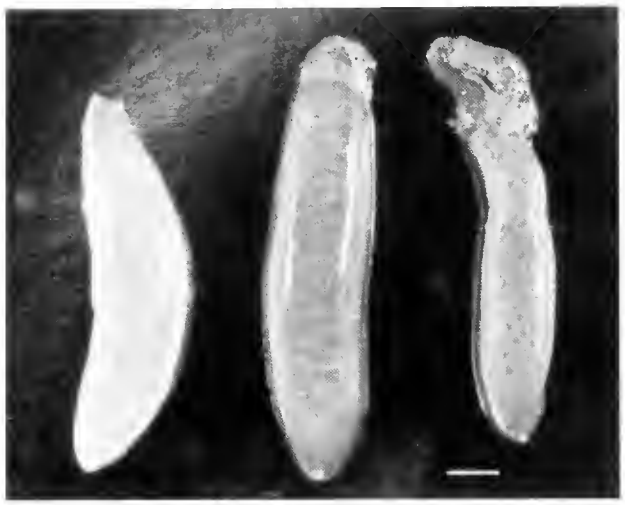

Figure 2. Aspect of *Loligo spp.* egg mass types found in the Atlantic coast of Patagonia. Left: type 1 egg capsule from Beagle Channel, Center: type 1 *Loligo sp.* egg capsule from Nuevo Gulf, Right: type 2 egg capsule from Nuevo Gulf (scale bar = 6 mm).

L. sanpaulensis was 1.2 (1.2–1.3 mm; $n = 200$). The dry weights of 100 oocytes were 0.10 g for each of the three replicates of *L. gahi*'s oocytes and 0.03 g for those of *L. sanpaulensis*. Given that *L. gahi* and *L. sanpaulensis* are the only loliginids that inhabit the waters of northeastern Patagonia (Castellanos & Cazzaniga 1979, Inada et al. 1986), the striking correspondence between the sizes and weights of each egg type and the mature oocytes of either species make it possible to state that the type 1 egg masses belong to *L. gahi* and type 2 egg masses belong to *L. sanpaulensis*.

From the egg masses obtained in Bridges Islands (Fig. 1; Table 1), those found in August 1998 showed eggs identical in size to the *L. gahi* eggs from Nuevo Gulf (average 2.2 mm, range 2.1–2.3 mm; $n = 200$). The egg mass found in the same locality in June 1997 (Table 1) showed eggs somehow bigger than those normally found in the type 1 egg masses (average 2.6 mm, range 2.3–3.0 mm; $n = 200$). Moreover, this was composed of two different groups of capsules showing eggs that were 2.3–2.6 mm and 2.6–3.0 mm. However, the number of eggs per capsule fell into the range reported for the type 1 egg masses (Table 1). The dry weight of each of the three 100-egg replicates taken from this egg mass was 0.20 g.

In Nuevo Gulf, *L. gahi* spawned almost continually throughout the year; February was the only month in which egg masses were not found (Table 1). According to historical registers (more than 10 years, hourly records) taken at Nuevo Gulf (unpublished data, Puerto Madryn's Tides Control Station, Hydrographic Service, Argentine Navy), the monthly average of daily minimum SST reaches a minimum in August (7.3°C), and the monthly average of daily maximum SST reaches a maximum in February (23°C). SST registered in Beagle Channel at the time of collection of type 1 egg masses (August 1998) was 5°C. These data show that *L. gahi* can spawn at temperatures as low as 5°C and that spawning could be limited at temperatures close to 23°C. Although the sampling procedure limits the quantitative estimation on spawning peaks of *L. gahi* in Nuevo Gulf, it is interesting that *L. gahi* egg masses with higher numbers of capsules were registered in September in both 1996 and 1997 (Table 1). Type 2 egg masses were found in Nuevo Gulf from March 1998 to May 1998 and in February 2000 (Table 1). The analysis of the embryonic stages found in these egg masses

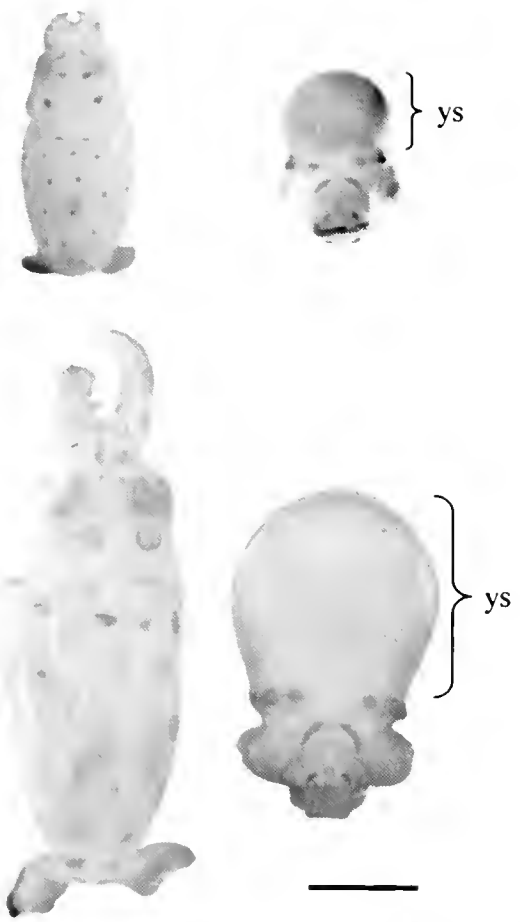

Figure 3. Compared aspect of the type 1 and type 2 *Loligo* fixed embryos. Upper left: type 2 embryo at stage 30; upper rigth: type 2 embryo at stage 21; lower left: type 1 embryo at stage 30; lower rigth: type 1 embryo at stage 21 (scale bar = 1 mm). ys: yolk sac. Embryonic stages following the scale of embryonic development of Arnold (1965).

suggests that the egg masses were actually deposited from March 1998 to April 1998 and in January 2000. These results show that the spawning season of *L. sanpaulensis* in the study area extends from summer to early fall. During this period, the monthly average of daily minimum SST reaches a minimum in April (12°C), and the monthly average of daily mean SST ranges between 15°C (April) and 17.5°C (February).

DISCUSSION

It has been observed that some loliginids deposit their egg masses on the ropes and PVC pipes used as traps for octopuses (Porteiro & Martins 1992, Ré et al. 1996). Also, artificial egg masses such as those used in this work have been reported to cause a visual stimulus for loliginids to mate and spawn (Arnold & Williams Arnold 1977, Yang et al. 1986, Vecchione 1988). The devices deployed in this study to examine the laying activities of the Loligo species present in Nuevo Gulf are a simplification of those traps. These structures stimulated the spawning of *L. gahi* but did not show any results with *L. sanpaulensis*. This seems reasonable, considering that *L. gahi* deposits its egg masses on hard substrata and *L. sanpaulensis* spawns on soft bottoms. A distinct selection of substrata for egg laying has also been observed in two sympatric loliginids in the Gulf of Mexico, *L. pealei* selecting hard substrates and *L. plei* (Blainville, 1823) preferring soft

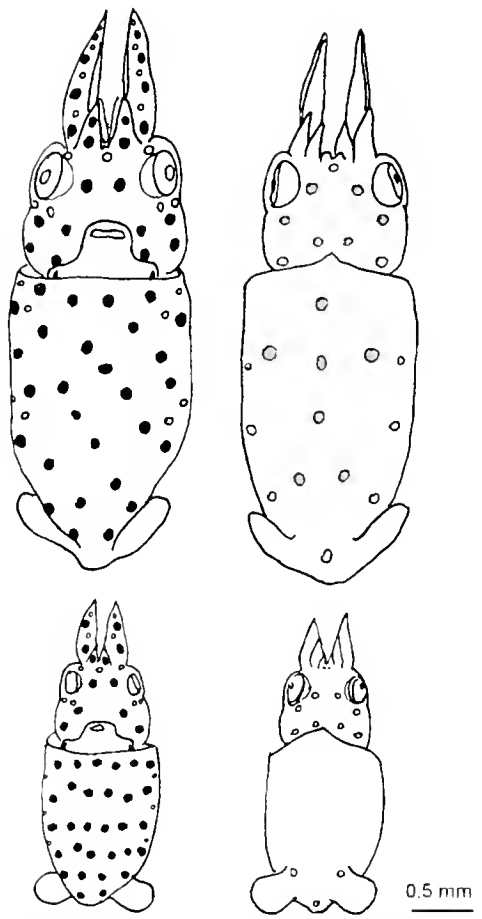

Figure 4. Chromatophore arrangements on the ventral (left) and dorsal (rigth) surfaces of the *Loligo spp.* hatching paralarvae from coastal waters of Patagonia. Top: type 1 paralarva, bottom: type 2 paralarva. Black circles represent red chromatophores, gray circles represent brown chromatophores and empty circles represent yellow chromatophores.

substrates (Vecchione 1988). Arkhipkin et al. (2000) found egg masses of *L. gahi* attached to no other substrate than kelp and concluded that the spawning sites of the species could be limited to shallow waters. In the present work, egg masses of *L. gahi* have been found attached not only to kelp but also to other types of hard substrate.

The structure of both species' egg masses, several capsules enclosing a row of eggs arranged in a coiled pattern along their longitudinal axle, is typical of Loligo species (Arnold & Williams Arnold 1977). The number of capsules per egg mass is variable for *L. gahi* and *L. sanpaulensis* egg masses; this variability is probably related to the size and physiological condition of the mother. This has also been observed in *L. vulgaris* reynaudii (Lamark, 1798) by Sauer et al. (1993), who found concentrations of egg masses more than 3 m in diameter surrounded by smaller ones (1–10 capsules per egg mass), and by Vecchione (1988), who observed Loligo sp. egg masses in the Gulf of Mexico that were made up of 10–40 capsules. However, as it has been observed in the present study, the variability could in part be the result of the deposition of multiple egg masses on a common mass by more than one female. Also, it should be noted that even when most egg masses were considered as individual egg masses, it is possible that these were deposited by more than one female within a brief period of time, so they could not be distinguished from each other on the basis of embryo maturity. This has also been suggested by Arkhipkin et al. (2000) who found 6–141 capsules per egg mass in *L. gahi*.

The number of eggs per capsule in the egg masses of *L. gahi* is comparable to that reported for other loliginids, such as *L. duvaucelii* (D'Orbigny, 1848) (125–150 eggs per capsule; Asokan & Kakati 1991), *L. forbesi* (Steenstrup, 1856) (39–52 eggs per capsule; Porteiro & Martins 1992), and *L. vulgaris reynaudii* (148 ± 37 [mean ± SD] eggs per capsule; Sauer et al. 1993). The number of eggs per capsule reported in this study is comparable to that found by Guerra et al. (2001) (50–60 eggs per capsule) from a 12-capsule egg mass of *L. gahi* found in Reñaca, Chile (32°58′S, 71°32′W). Also, the mean number of eggs per capsule observed in the present work (69 eggs per capsule) is similar to that reported by Arkhipkin et al. (2000) for the same species (71 eggs per capsule). The number of eggs per capsule of *L. sanpaulensis* is comparable to that for *L. plei* (200–300 eggs per capsule) reported by Waller and Wicklung (1968).

The egg-size range of *L. opalescens* (Berry, 1911) (2.0–2.5 mm; Fields 1965) shows the greatest resemblance to that of *L. gahi*. Other species with close egg-size ranges are *L. vulgaris* (2.3–2.7 mm) (Worms 1983, cited in Baeg et al. 1992) and *L. bleekeri* (Keferstein, 1866) (2.6–2.7 mm; Baeg et al. 1992). The size range observed in the eggs of *L. gahi* from Nuevo Gulf and the egg mass found in Bridges Islands in August 1998 (2.1–2.3 mm) is within the range reported by Arkhipkin et al. (2000) (2.0–2.5 mm) from egg masses found in the Falkland (Malvinas) Islands, and the size range from the eggs found in Bridges Islands in June 1997 (2.3–3.0 mm) is comparable to that reported by Guerra et al. (2001) from the eggs found in Reñaca, Chile (2.6–3.1 mm). On the other hand, the size range of the *L. sanpaulensis* eggs falls within the range reported for the Northeastern Atlantic species *L. pealei* (1.1–1.6 mm; Summers 1983, cited in Baeg et al. 1992).

The chromatophore arrangements displayed by the hatching paralarvae of *L. gahi* and *L. sanpaulensis* were easily distinguishable from each other. The pattern found in *L. gahi* closely resembles that reported by McConathy et al. (1980) for *L. opalescens*, and the pattern found in *L. sanpaulensis* is similar to that observed by the same authors in *Lolliguncula brevis* (Blainville, 1823). The pattern of chromatophore arrangements reported by Arkhipkin et al. (2000) for the paralarvae of *L. gahi* is similar to that found in this study. However, this authors omitted two yellow chromatophores placed on the ventral surface of the head, anterior to the eyes, that were regularly observed in the *L. gahi* hatchlings from this study, both from Nuevo Gulf and Bridges Islands, and in other loliginids (Naef 1928, McConathy et al. 1980, Baeg et al. 1992, Blackburn et al. 1998). Also, Arkhipkin et al. (2000) incorrectly report the presence of brown chromatophores on the ventral surface of the hatching paralarvae, which are actually red, and the presence of orange chromatophores, which are actually yellow (orange chromatophores are present only in earlier stages of the embryonic development).

L. gahi shows a year-round spawning season in Nuevo Gulf, which could be limited at the depth range covered in this study (0–15 m) by the maximum SST of the hottest month. Continuous spawning throughout the year has also been reported for *L. vulgaris* reynaudii (Sauer et al. 1992) from South Africa and *L. forbesi* (Lum Kong et al. 1992) from Irish waters. The observation of two peaks of recruitment of *L. gahi* to the Falkland (Malvinas) Islands fishery has led some authors to consider two major spawning peaks for that area (Patterson 1988, Hatfield et al. 1990).

Recently, a third recruitment peak has been identified (Agnew et al. 1998, Hatfield & Murray 1999). The hypothesis of a spawning peak in September for *L. gahi* in Nuevo Gulf, on the basis of this study's preliminary observations on the size of the egg masses, agrees with the observations of Portela et al. (1994), who reported maximum proportions of spawning *L. gahi* individuals in September between 42°S and 49°S during a survey conducted from March to October 1989.

On the basis of the results of the egg mass survey in Nuevo Gulf, it can be stated that the spawning activity of *L. sanpaulensis* near the southern limit of its geographic distribution is restricted to summer. Unpublished data on the reproductive cycle of *L. sanpaulensis* in Northern Patagonia on the size and maturity structure of the adult and juvenile population (Barón & Ré, Pers. Comm.) is consistent with this conclusion. Previous studies on the reproductive cycle of *L. sanpaulensis* in fishing areas of central Argentina (Mar del Plata, 38°S) and Brazil (Cabo Frio, 21°S) indicated two spawning peaks per year (Vigliano 1985, Costa & Fernandes 1993). However, an extended spawning period for *L. sanpaulensis* throughout the year has been considered for southern Brazil in a more recent study (Andriguetto & Haimovici 1996). In Nuevo Gulf, spawning seems to be limited by water temperature below 12°C and facilitated by a monthly average of daily mean temperature in the range of 15–17.5°C. This temperature range is in agreement with the observations of Andriguetto and Haimovici (1996) who reported the finding of undetermined Loligo egg masses, presumably of *L. sanpaulensis*, in Southern Brazil at bottom temperatures of 17.5°C–17.8°C.

The differences in the sizes and weights of the eggs in the egg mass found in Bridges Islands in July 1997 cannot be fully explained on the basis of the present information. The existence of two groups of capsules enclosing eggs with different size ranges but the same stage of development suggests that this was actually a multiple egg mass deposited by two females within a brief time interval. Given that the number of eggs per capsule of this egg mass is within the range observed for type 1 egg masses, this could be a *L. gahi* egg mass adapted to the low temperature conditions of the Beagle Channel. On the other hand, it could be thought of as the egg mass of another Loligo species. Filippova (1969, cited in Castellanos & Cazzaniga 1979) postulated the existence of two different taxonomic entities within *L. gahi* (*L. gahi* in waters of the Pacific and *L. patagonica* in the Atlantic). However, Castellanos and Cazzaniga (1979) and Brakoniecki (1984) presented evidence that *L. patagonica* is a junior synonym of *L. gahi*.

The present work shows the wide ranges of latitude and temperature suitable for the spawning activity of *L. gahi* along the Patagonian Coast and the narrow range of temperature at which *L. sanpaulensis* can reproduce near the southern limit of its distribution. Further studies on the spawning grounds of *L. gahi* and *L. sanpaulensis* must emphasize quantitative estimations to provide predictive data on the recruitment patterns of both species.

ACKNOWLEDGMENTS

I am grateful to the personnel of the vessel Lago Musters (Prefectura Naval Argentina) for their assistance in the survey of egg masses in Nuevo Gulf and to Mr. Hector Monsalve, Dr. Raúl Gonzalez, and Dr. Alejandro Petovello, who provided part of the material used in this study. I appreciate the support given by Dr. María E. Ré and the valuable comments given by Dr. Manuel Haimovici, Dr. Nestor Ciocco, Dr. José "Lobo" Orensanz, and two anonimous referees.

DIGESTION OF CELLULOSE BY STOMACH HOMOGENATES OF GREEN ABALONE (*HALIOTIS FULGENS*)

ALFREDO ENRÍQUEZ,[1] MARÍA TERESA VIANA,[2,*] CARLOS VÁSQUEZ,[3] AND ARMANDO SHIMADA[4]

[1]*Facultad de Ciencias Marinas, Universidad Autónoma de Baja California, Ensenada, B.C., México;* [2]*Instituto de Investigaciones Oceanológicas, Universidad Autónoma de Baja California, Ensenada, B.C., Mexico;* [3]*Dirección Técnico-Administrativa, Dirección General de Zoológicos de la Ciudad de México, Chapultepec, D.F., México;* [4]*Facultad de Estudios Superiores-Cuautitlán, Universidad Nacional Autónoma de México, Ajuchitlán, Qro., México*

ABSTRACT Three experiments were conducted to study the cellulase activity of stomach homogenates of green abalone, with and without antibiotics added. Forty-eight previously frozen stomachs from wild abalone adults were thawed and individually homogenized. Four cultured abalone adults maintained under a balanced diet containing cellulose were killed and the fresh stomach samples processed. Cellulase activity was estimated through the production of glucose, incubating the homogenate from each organism with cellulose. To determine the effect of bacteria, each stomach was incubated (at 25°C for 20 h) in a completely randomized design, with and without an antibiotic mixture. For a time series measurement (exp. 2), four homogenates from wild abalone were used; the incubation mixture was followed up taking samples at 0, 1, 2, 4, 8, 16, 20, 32, 64 and 72 h. The latter samples were also used to measure the enzymatic activity before and after a 72-h incubation, in the absence of antibiotics (exp. 3). Initial bacterial counts in the wild abalone homogenates were 459 colonies per mL. In the presence of the antibiotic mixture, no bacterial growth was observed. Initial cellulase activity was 1.6 Units. Cellulose degradation figures were low, even in the absence of antibiotics, indicating the low dependence of abalone on the nutrients derived from the digestion of the cell walls. Still, the addition of antibiotics depressed the digestion of cellulose (14.5 *vs.* 10.2%), suggesting the importance of live bacteria in the digestion process, and that the majority of the degraded cellulose is perhaps acted upon by endogenous enzymes. The time series experiment of samples from wild abalone, with and without antibiotics, showed quadratic effects on cellulose digestion $y = 7.55 + .29h - .005\ h^2$ ($r^2 = .2212$), but no significant differences between treatments. The gradual increase in the digestion of cellulose, followed by a plateau is similar to what happens in ruminant digestion. The initial and final enzyme activity without antibiotics showed a significant reduction of 41.1% for the wild abalone whereas in cultured abalone a 50.9% significant reduction was observed. It seems that the cellulase complex enzymes present in the homogenates remain active after 72 h of incubation, even though their activity is lowered by about one half. Although the use of antibiotics assure the absence of live bacteria in the incubation mixture, the cellular enzymes possibly freed by the effect of the antibiotics could still be active for up to 72 h after the microbes are no longer viable. Thus the enzymatic activity attributed to the stomach itself could still be confounded.

KEY WORDS: green abalone, *Haliotis fulgens*, cellulose, digestion, bacteria, antibiotics

INTRODUCTION

The information on the nutritional physiology of the abalone, specifically in relation to their capability to digest and metabolize polysaccharides such as cellulose, is scarce. Uki et al. (1985) and Uki and Watanabe (1992) established that abalone had a limited capacity to digest cellulose as their growth rate was inversely related to increased levels of dietary cellulose (from 0 to 20%). However, it has been observed that abalone grown in banks with predominant sea grass, with higher cellulose content, appear to be bigger and healthier than those grown in areas were kelp is the predominant vegetation. Monje and Viana (1998) compared two purified diets, one containing 19% cellulose and 1% sodium alginate and a second one in which cellulose was substituted with sodium alginate. Although both diets resulted in similar growth rates, the group fed the cellulose-based diet had higher cellulase and alginase activities than those fed the sodium alginate.

Leighton (1968) stated that the enzymes involved in the digestion of complex carbohydrates were secreted in the hepatopancreas. In contrast, Erasmus et al. (1997) suggested that bacteria might play a role in the digestive process of the gastropod, since several microbial species with cellulase activity could be detected in the digestive tract of the abalone (*H. midae*); however they registered cellulase activity even in gnotobiotic organisms.

The aim of the present experiments was to study the cellulase activity of stomach homogenates of abalone, with and without antibiotics added, using a crystalline form of cellulose as substrate.

MATERIALS AND METHODS

Forty-eight stomachs were obtained from wild abalone adults, harvested near the "Emancipación" Fishery Cooperative in Baja California. The stomachs were placed in layers on ice, and frozen at −75°C until used. They were later thawed slowly in temperate water, their pH and ion strength measured, and then individually homogenized.

Four cultured abalone adults that had been maintained under a balanced diet (Table 1) containing 5% cellulose were killed and the stomach samples immediately processed as mentioned above.

Cellulase activity was estimated using the methodology described by Worthington (1988). Where an aliquot from the stomach homogenate from each organism was incubated with 300 mg α-cellulose in the presence of a .05 M phosphate buffer solution at pH 5.5, and 37°C. After 2 h, the reaction was colored with an anthrone-H_2SO_4 solution and the production of glucose measured by spectrophotometer (Genesis 2000) at 625 nm. One unit releases 0.01 mg glucose per hour from microcrystalline cellulose at 37°C, pH 5.5, per mg of stomach homogenate (wet weight).

Sodium benzoate	2
BHT[6]	4

[1] 60% protein kindly supplied by Productos de Ensenada, México.
[2] Made from tuna-fish viscera, given as dry matter basis.
[3] Maseca, produced in Mexico.
[4] Alphacel, α-cellulose.
[5] As recommended by Uki and Watanabe (1992), kindly supplied by Roche, Mexico.
[6] Butylated Hydroxytoluene.

To determine the effect of the bacteria present in the homogenates, each stomach was incubated (at 25°C for 20 h) in a completely randomized design, with and without an antibiotic mixture as recommended by Erasmus (1996): chloramphenicol (250 μg/mL), cephalosporin (250 μg/mL) and ampicillin (600 μg/mL). At the end of the incubation a 1-mL sample was taken and after centrifugation (1880 g) the supernatant was used to determine glucose through the procedure indicated previously. The effect of the presence of the antibiotic mixture was assessed using the following calculation:

Relative digestibility reduction = [(dig. a − dig. n/a) · 100]/ dig. n/a

where: (dig. a) is the digestibility with antibiotics and (dig. n/a) the digestibility without antibiotics.

The number of bacterial colonies with and without antibiotics was determined before and after incubation of the stomach sample. Thus, a Zobell media was used by blending agar (1.5 g/100 mL), peptone (.5 g/100 mL), yeast extract (.1 g/100mL) and α-cellulose .2g/100 mL, mixed with filtered seawater to distilled water at a ratio of 1:3 v/v at pH 5.5. The Petri dishes were incubated at 25°C for up to two days, with and without antibiotics in the same proportion as indicated previously. Cellulase activity from the growing bacteria was corroborated using the Congo red procedure (Teather and Wood 1982).

For a time series measurement (experiment 2), four homogenates from wild abalone stomachs were used; the incubation mixture was followed up taking samples at 0, 1, 2, 4, 8, 16, 20, 32, 64 and 72 h. Glucose was determined as indicated previously and the glucose produced over time was related to the cellulase activity.

The latter samples were used to measure the enzymatic activity before and after a 72-h incubation, in the absence of antibiotics (experiment 3).

Statistical Analysis

A one-way ANOVA test was used to compare the relative digestibility reduction in stomach contents with and without antibiotics and to compare the initial and final enzyme activity in cultured and wild abalone without antibiotics after 72 h of incubation. Figures given in percentage were transformed to their arcsine sqr (y) to be analyzed. For the time series a quadratic and linear regression model was used to compare the slopes with a variance analysis to estimate the best adjustment according to Zar (1999). The SAS program was used to analyze the data.

RESULTS

The initial bacterial counts in the wild abalone homogenates were 459 colonies per mL of stomach. In the presence of the antibiotic mixture, no bacterial growth was observed. The initial cellulase activity of wild abalone homogenates was 1.6 Units. The *in vitro* digestibility of cellulose after 20 h incubation was lower when the antibiotic mixture was present (14.5 *vs.* 10.2%, respectively) although the difference was not significant ($P = .107$; $F = 2.666$). The relative digestibility reduction was 29.7% (Table 2).

The time series experiment of samples from wild abalone, with and without antibiotics (Table 3), showed quadratic effects on the digestion of cellulose $y = 7.55 + .29h - .005h^2$ ($r^2 = .2212$), but no significant differences between treatments. The estimated equations were $y = 8.35 + .31h - .005h^2$ for the treatment without antibiotics and $y = 6.76 + .29h - .004h^2$ for the treatment with antibiotics; the statistical analysis of these equations showed similar slopes.

For the cultured abalone, with and without antibiotics, there was also a quadratic effect, with significant differences ($P < .05$) between 4 and 16 h.

The initial and final enzyme activity without antibiotics showed a reduction of 41.1% ($P = .032$) for the wild abalone whereas in the cultured abalone a 50.9% ($P = .046$) reduction was observed (Table 4).

DISCUSSION

Mammalian cellulose-digesting herbivores can be divided into two groups: those who depend heavily on the resulting metabolites, and the ones in which the process only supplements their

nutritional budget. Still, both groups are unable to degrade cellulose with their own enzymes, relying instead on symbiotic microorganisms to perform the process. In any case, the digestibility of cellulose, which varies according to a number of factors (Merchen and Bourquin 1994), can be expected to be in the 40-60% and the 0-20% ranges for both animal groups, respectively (Van Soest 1994).

Symbiotic bacteria of mammalians' guts digest cellulose by attaching themselves to the substrate and then liberating the respective enzymes, which are diffused into the complex structural matrix of cellulose. These enzymes are produced either extracellularly or bound in the membrane of microbes. However, when the microbial cells are destroyed, the freed enzymes might still act directly on the cellulose molecules. For example, the ampicillins and cephalosporins used here, act on the bacteria by the activation of enzymes that destroy the cell wall, whereas chloramphenicol acts inhibiting bacterial protein synthesis.

In the experiment reported here, cellulose degradation figures were somehow low, even in the absence of antibiotics, which could be an indication of the low dependence of abalone on the nutrients derived from the digestion of the cell wall component. Still, the addition of the antibiotic mixture depressed the disappearance of cellulose by around one third, suggesting the importance of live bacteria in the digestion process, and that the majority of the degraded cellulose is perhaps acted upon by endogenous enzymes.

Erasmus et al. (1997) obtained bacteria-free abalone after immersing them for 72 h in sea water containing an antibiotic mixture. Unfortunately, after several attempts to get gnotobiotic *H. fulgens* in our lab, we were not able to repeat their procedure, either by the addition of antibiotics to the water or in the food. In all cases a considerable amount of bacteria appeared in the stomachs.

Moreover, to determine cellulase activity, Erasmus et al. (1997) used carboxymethyl cellulose, a chemically modified soluble presentation of cellulose, as substrate to determine cellulase activity. It is known that any form of cellulose that is either acid or alkali-treated has little effect on the overall cellulase system for most of the known microorganisms (Worthington 1999). The enzymatic mechanism whereby certain microorganisms can quite rapidly and completely degrade cellulose is not completely understood. However, according to Worthington (1999), two steps involved in the degradation are proposed: first, a pre-hydrolytic step wherein anhydro-glucose chains are swollen or hydrated, involving an enzyme designated C_1. The second step involves the hydrolytic cleavage of the now susceptible polymers either randomly or endwise with an enzyme complex termed $C\chi$ consisting of exo and endo β-1,4 glucanases and β-glucosidase (cellobiase) that attack soluble derivatives or cellulose that has been swollen by acid or alkali. Therefore it is recommended that in order to test true cellulase activity, the most crystalline form of cellulose available be used. In the present work α-cellulose was used.

The effect observed with the homogenates from the wild organisms in the first 32 h of incubation, is similar to what might be expected to occur in the digestive tract of the large mammalian herbivores (Van Soest 1994); that is, a gradual increase in the digestion of cellulose (as the so-called digestion rate in ruminants), followed by a plateau (equivalent to what is known as the extent of the fermentation in ruminants). The low figures for the 64 and 72-h samples could indicate the destruction of the glucose formed from cellulose, due to the long incubation period.

The results of experiment 3 could be interpreted in two ways: either that the cellulase enzymes present in the stomach homogenates remain active even after 72 h of incubation, although their capability to cleave the substrate is lowered by about one half; or that the final product (*i.e.* glucose), used as indicative of the cellulase activity, was partially spent as in the case of experiment 2. If this is the case, then the activity against carboxymethil cellulose presented by Erasmus et al. (1997) in stomach content after the abalone were treated with antibiotics for 72 hours could not be regarded as indicative of endogenous enzymes participation but to a remnant activity in the stomach.

Finally, it is important to stress that although the use of the

TABLE 4.

Initial and final enzyme activities from wild and cultured abalone stomach homogenates, without antibiotics, after 72 hours of incubation.

antibiotic mixture assured the absence of live bacteria in the incubation process, the cellular enzymes freed by the effect of the antibiotics could still be active even at 72 h after the microbes were no longer viable. Thus the enzymatic activity attributed to the stomach itself could still be confounded.

REPRODUCTIVE CHARACTERISTICS OF THE ARCHAEOGASTROPOD *MEGATHURA CRENULATA*

PETER G. BENINGER,[1]* ROZENN CANNUEL,[1] JEAN-LOUIS BLIN,[2] SÉBASTIEN PIEN,[2] AND OLIVIER RICHARD[2]

[1]*Laboratoire de Biologie Marine, ISOMer, Faculté des Sciences et Techniques, Université de Nantes, 44322 Nantes Cedex, France;* [2]*Syndicat Mixte pour l'Equipement du Littoral, Zone conchylicole, 50560 Blainville sur Mer, France*

ABSTRACT A histological and histochemical study was performed on individuals of the archaeogastropod *Megathura crenulata* sampled in the field, in order to ascertain the fundamental features of reproductive biology in this species. Basic aspects addressed were gonad and gamete structure, nature of vitelline reserves, and composition of oocyte coat. Stereological counts and oocyte measurements were performed to obtain a quantitative assessment of the reproductive cycle from June 1999 to June 2000. No simultaneous hermaphrodites were observed. The gonad structure of *M. crenulata* consisted of traversing trabeculae from which gametes developed centrifugally. The gonads of both males and females were homogeneous, allowing reliable data to be obtained from a single histological sample of each individual. Mature gametes greatly dominated the profile throughout the study period; coated oocyte diameters were also very stable. These techniques, routinely applied to the study of reproductive cycles, did not allow the identification of spawning preparedness in this species. Vitelline reserves were dominated by non-staining (putatively lipid) vacuoles; no appreciable quantities of glycogen were observed. The oocyte coat was chiefly composed of acid mucopolysaccharides, conferring both mechanical and antimicrobial protection, as well as limiting egg and larval dispersal.

KEY WORDS: *Megathura crenulata*, Gastropoda, gonads, gametes, reproductive cycle, histochemistry

INTRODUCTION

Many marine natural products present biological activity in humans, and are used in medical testing or in pharmaceuticals (Munro et al. 1987, Ireland et al. 1989, Kobayashi et al. 1989, Suffness et al. 1989, Faulkner 2000). The archaeogastropod *Megathura crenulata* is a keyhole limpet native to the California Pacific Coast, with a reported range from Mendocino County (40°N; 124°W) to Isla Asuncio (27°N; 115°W). Keyhole limpet hemocyanin (KLH) of this organism is used in the treatment of certain forms of bladder cancer (Harris & Markl 1999, 2000). It is thus of considerable medical and economic interest to rear this organism for extraction and purification of the active compound. This goal requires knowledge concerning essential aspects of *M. crenulata* biology, notably feeding, growth, and reproduction.

The sparse studies on reproduction in *M. crenulata* chiefly concern modes of fertilization, which is external and involves several hormonal agents (Tyler 1939, Webber 1977). The lack of data on the reproductive biology of *M. crenulata* may be contrasted with the relatively abundant information concerning the highly-prized abalones (*Haliotis spp*), which are commercially important, edible archaeogastropods (Newman 1967, Purchon 1968, Fretter 1984, Hahn 1989). The present study documents the gonad structure, oocyte histochemistry and reproductive cycle of *M.crenulata* in its natural habitat, with a view toward the long-term objective of cultivation.

MATERIAL AND METHODS

Specimen Collection and Dissection

The animals used in the present study were obtained from June 1999 to June 2000 from the subtidal zone off Long Beach, California (33°45′N, 118°10′W). The specimens were sent by air to France, where they were dissected and fixed in the SMEL (Syndicat Mixte pour l'Equipement du Littoral) laboratory in Blainville, Normandy. Five individuals were dissected each month, except in October 1999, when no sampling was possible. In order to verify the structural homogeneity of the gonad, the entire organ was removed in certain individuals of certain months, and several regions were examined (Table 1): a median region (M), a distal extremity (DE) and a proximal extremity (PE). For samples from February, May, and June 2000, tissue pieces were obtained from labelled L, M and R regions, allowing the distinction of left (L), median (M), and right (R) regions of the gonad. The types of histological sample are summarized in Table 1 for each individual and each sampling date.

Histological Techniques

In most cases, entire gonads were fixed in aqueous Bouin's solution. In an effort to improve fixation, small pieces of the gonad were fixed in March and April; however, the resulting sections showed that this provoked extensive leakage of gametes, such that the sections could not be used for males in either month, and for females in March. From February, May, and June 2000, in which the dissections allowed the distinction of three different regions of the gonad, histological samples were directly fixed. After rinsing for a minimum of 10 h and dehydration in an ascending ethanol–Bioclear® series, the biopsies were embedded in paraffin and sectioned at 7 μm.

Several staining protocols were developed for this study, based on Martoja and Martoja-Pierson (1967), Gabe (1968) and Vacca (1985), as indicated in Table 2. A modified Masson's trichrome protocol using fast green, trioxyhematein, and acid fuschin allowed the topological study of the gonads, distinguishing connective tissue, oocyte coat, cytoplasm, nucleus, chromatin, and nucleolus. Periodic acid–Schiff reagents with positive (oyster digestive gland) and negative (amylase-digested sections of gonad) controls were used to determine the eventual presence of glycogen in the oocyte cytoplasm, as well as neutral mucopolysaccharides (NMPS) in the oocyte coat. Alcian blue was used to determine the presence of acid mucopolysaccharides (AMPS) in the oocyte coat.

I: undetermined gonad region; M: median gonad region; P: proximal region of non-oriented gonad (organ previously removed from individual); D: distal region of non-oriented gonad; R: right region of oriented gonad; L: left region of oriented gonad.

Stereology

Stereological counts were performed in order to quantify the proportions of the different tissue types in the histological sections; variations in the proportions of the different tissue categories thus reflected variations in the different phases of reproductive activity (Weibel et al. 1966, Briarty 1975, Beninger 1987, Morvan & Ansell 1988, Pazos et al. 1996, Mayhew 2000); counts were performed on surfaces of measured area, using a 9×9 point matrix on a microscope projector.

In males, four tissue categories were identified for stereological purposes: trabecular tissue, developing gametes, mature gametes, and unoccupied space. In females, three tissue categories were identified: coated oocytes, non-coated oocytes, and trabecular tissue. Due to the loose nature of the female gonad tissue, it was impossible to determine whether observed unoccupied spaces were real or artefacts of gonad dissection. Stereolological counts were therefore performed only on areas without visible unoccupied space.

Nine counts were performed for each individual and region of the gonad, and the means (with 95% confidence intervals) of all male and female counts were plotted.

Oocyte Diameters

Oocyte diameters were measured for 30 coated oocytes for each female and for each gonad region, using a calibrated optical micrometer. In order to standardize the measurements, only oocytes in which the nucleolus was visible (approximately the center of the cell) were selected. The evolution of oocyte diameters could then be recorded throughout the year.

RESULTS

Males

Gonad Structure

The general structure of the male gonad is presented in Figure 1 area 1. The gonad was composed of connective tissue trabeculae, from which arise centrifugally the germ cells, first visible as developing aflagellate gametes, and then the mature flagellate spermatozoa. The mature spermatozoa occupied the majority of the sectional area (Fig. 1 area 1, Fig. 2).

Stereology

Testicle homogeneity was verified in 1 to 3 individuals from July, August 1999 and January, February and May 2000, using stereological counts. The results shown in Fig. 2 indicate that the male gonad was structurally homogeneous and gametogenetically synchronous. Reliable data for histological study may therefore be obtained from only one histological sample per individual.

The male gonad presented a stable histological profile throughout the study period from July 1999 to June 2000. Mature spermatozoa occupied almost the entire gonad, with mean volume fractions of 0.77 (May 2000) to 0.88 (November 1999). In comparison, developing gametes occupied a low proportion of the gonad, from 0.095 (November 1999) to 0.16 (July 1999). Trabec-

TABLE 2.

Summary of stains used, and celullar and molecular components targeted.

Stain used	Structures and molecules targeted	Cellular and tissue constituents
Acid fuschin	Cytoplasmic granules	Cytoplasmic granules
Fast green	Reticulate fibres, collagen	Connective tissue
Trioxyhematein	Nucleic acids	Nucleus, nucleolus and chromatin
PAS-alcian blue	Neutral and acid mucopolysaccharides; glycogen	Oocyte coat Possible glycogen

ular tissue occupied a low and stable proportion of the testicle (approximately 0.03). Unoccupied space was rare (Fig. 3).

Females

Gonad Structure and Oocyte Histochemistry

The structure of the female gonad is shown in Figure 1, area 2. Trabeculae consisted of connective tissue (Fast Green positive) and were often masked by the acid fuschin. Uncoated oocytes adhered to the trabecular tissue and were small (approximately 25 μm) their cytoplasm was less intensely stained compared to coated oocytes. Unstained regions of trichrome-stained sections corresponded to the oocyte coat, which like the oocytes themselves appeared to be of constant dimension when the sectional plane passed through the nucleus. The cytoplasm of coated oocytes stained intensely with both trioxyhematein and acid fuschin, indicating the presence of numerous cytoplasmic globules. Many unstained globules (poorly visible in photographs due to the great staining heterogeneity of the sections) were present in the cytoplasm of the coated oocytes (Fig. 1 areas 2, 5, 6). Of the major biochemical tissue constituents, Masson's trichrome does not stain lipids (which are extracted during section preparation) or AMPS; as the globules were not alcian-blue positive (Fig. 1 areas 3–6), they were very probably lipid in nature.

The intensity of the cytoplasmic staining obscured the nucleus of those oocytes for which the sectional plane did not pass through the nucleus. When visible, the large nucleus (approximately 75 μm) presented dispersed heterochromatin and a single nucleolus (Fig. 1 area 2).

The oocyte coat appeared to be composed of two layers: a high-density proximal layer and a lower-density distal layer (Fig. 1 area 2). Staining with alcian blue confirmed this structure, and identified the principal coat constituent as AMPS (Fig. 1 areas 3–6). Counterstaining with trioxyhematein was extensive in the cytoplasm, indicating the presence of large quantities of nucleic acids, suggesting considerable anabolic activity (Fig. 1 areas 3, 4). The negative PAS reaction indicated both an absence of appreciable quantities of glycogen in the oocytes, and an absence of NMPS in the oocyte coat (Fig. 1 areas 5, 6).

Stereology

Ovarian homogeneity was verified in June, August, September, November and December 1999, and in February, April, May and June 2000. The near-identical volume fractions for the three identified ovary regions demonstrated the histological homogeneity of this organ (Fig. 4). These data confirm that the female gonad was structurally homogenous and gametogenetically synchronous. As was the case for the male gonad, representative histological data may thus be obtained from a single histological sample per individual. Similarly, the female gonad showed a stable tissue profile throughout the sampling period. Coated oocytes represented the great majority of the mean volume fraction (Fig. 5), from 0.83 (June 1999) to 0.94 (November 1999). Uncoated oocytes represented a small mean volume fraction, from 0.01 (November 1999) to 0.04 (June 1999). The mean volume fraction of trabecular tissue was also small: 0.035 (May 2000) to 0.12 (June 1999).

Oocyte Diameters

Given the homogeneity of the ovary, oocyte diameters were pooled for all females of a given sampling date. Mean diameters varied only slightly, from 125 to 135 μm without the coat (Fig. 6).

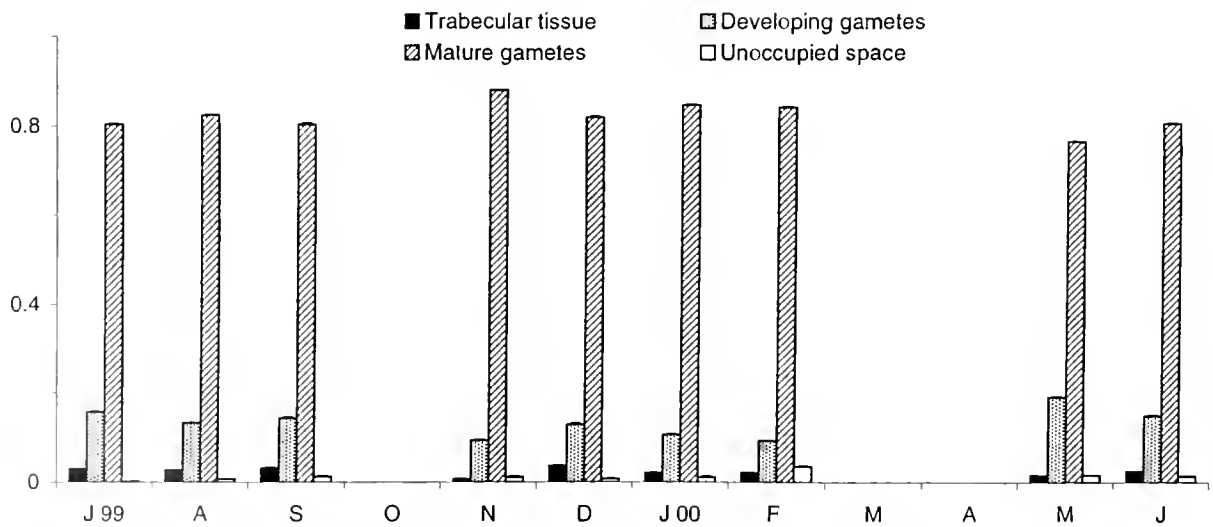

Figure 3. ***M. crenulata.*** **Evolution of tissue volume fractions in males, July 1999 to June 2000. The 95% confidence intervals are too small to be seen. Data unavailable in October, March, and April due to sampling difficulties.**

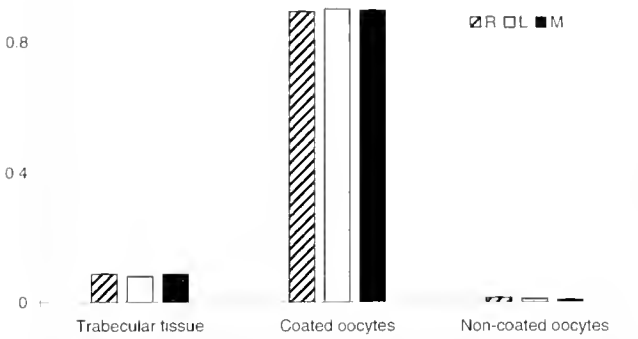

Figure 4. ***M. crenulata.*** **Volume fractions of tissue categories in right (R), left (L), and median (M) gonad regions of three females sampled in February 2000. The 95% confidence intervals are too small to be seen.**

This difference was not statistically significant (parametric ANOVA, normality and heteroscedasticity verified, $P \leq 0.05$).

DISCUSSION

To our knowledge, the results of the present study constitute the first report on the gonad structure, reproductive cycle and oocyte histochemistry in *Megathura crenulata*. A much more abundant literature exists for the commercially exploited archaeogastropods of the family Haliotidae, to which frequent reference will be made.

Gonad Structure

The gonad structure of *M. crenulata*, with gametes developing centrifugally from traversing trabeculae, resembles the well-known example of the Haliotidae (Newman 1967, Young & DeMartini 1970, Cochard 1980). In all of these cases, no ciliated evacuating ducts were observed; gametes are presumably expulsed via contractions of the gonad tegument, as is in *H. midae* (Newman 1967).

No simultaneous hermaphrodites were observed in any of the specimens studied; the dominant possible sexual modes for *M. crenulata* are therefore either gonochoric or successive hermaphrodite. Most prosobranchs are gonochoric, but there are a small number of hermaphroditic species (Fretter & Graham 1964, Fretter 1984). Complete resolution of this question in *M. crenulata* will require extensive sampling and long-term rearing.

Gonad structure was shown to be homogeneous for both male and female *M. crenulata*, as is also the case for *Haliotis midae* (Newman 1967). This result will facilitate future studies on the gonad of this species. By standardizing the histological sampling zone, it should be possible to reduce even further the residual inter-individual variation.

Reproductive Cycle

The marked stability of both the male and female *M. crenulata* gonad histological profile throughout the sampling period, as well as the uniform oocyte size, preclude the use of either criterion in determining gamete maturity, or even the state of spawning readiness of the gonad. The stable histological profile raises an interesting possibility: spawning readiness may depend on fine-tuning oocyte reserves rather than on synchronizing protracted periods of vitellogenesis. This is in contrast to the situation in the Haliotidae. A bimodal oocyte size distribution was observed in *H. midae* (Newman 1967); in *H. roei*, three oocyte maturation stages, characterized by different diameters, were observed (Shepherd & Laws 1974). Several oocyte sizes co-exist in *H. tuberculata*, with progressive growth from January to mid-July (Cochard 1980). Similarly, marked changes in histological profile characterize the reproductive cycle of *H. midae* males (Newman 1967). Whereas mature spermatozoa were found in *H. rufescens*, this appeared to correspond to a lack of variation in gonad indices and therefore year-round dribble spawning (Young & DeMartini 1970). Similarly, *H. asinina* synchronously spawns every two weeks on the Southern Great Barrier Reef (Jebreen et al. 2000). In the present case, the gonad appears ready to spawn at any moment in the reproductive cycle. The true state of gamete maturity must therefore be ascertained by other means, as suggested below.

A crude indicator of spawning readiness could involve determination of a gonosomatic index (DeVlaming et al. 1982); indeed, despite the uniform histological profile, considerable variations in gonad volume were observed over the sampling period in the few individuals dissected for histological processing. However, such a

technique requires the sacrifice of relatively large numbers of animals and is therefore not feasible in the context of the commercial exploitation of this species reared in captivity for repeated extraction of valuable hemolymph.

Oocyte Histochemistry

The presence of an oocyte coat, observed in mature oocytes of *M. crenulata*, is typical of archaeogastropods (Newman 1967, Cochard 1980). In gastropods with coated oocytes, gamones intervene in the modification of the coat to permit fertilization (Fretter & Graham 1964, Webber 1977, Fretter 1984). The results of the present study establish AMPS as a dominant component of the oocyte coat in *M. crenulata*. AMPS possess several chemical and mechanical properties which may confer important advantages to the oocytes: (i) Due to the high viscosity of AMPS (Beninger & St-Jean 1997, Davies & Hawkins 1998), they provide mechanical protection to the oocytes; (ii) AMPS reduce frictional resistance, thus allowing better water movement (Hoyt 1975, Daniel 1981, Davies & Hawkins 1998) over the egg masses, and hence improved gas exchange and metabolic waste removal. The reduced frictional resistance would also reduce the probability of dislodging the egg masses; (iii) AMPS possess anti-microbial properties (Sasikala & Subramoniam 1987, Subramoniam 1991, Beninger & Larocque 1998), potentially conferring protection from opportunistic microbes in the egg masses; (iv) the relatively high density of the AMPS coats could act to confer negative buoyancy to the otherwise positively buoyant (due to the high lipid content) oocytes, allowing the egg masses to remain on the substrate rather than in the water column. This characteristic is important in species which limit propagule dispersal; further studies on the reproductive biology of *M. crenulata* could address this possibility; (v) AMPS adhere to and agglutinate particles strongly, as shown in the context of bivalve particle processing (Beninger & St-Jean 1997). This property would once again reduce the dispersal of the oocytes, which are oviposited as egg masses.

The lack of positive PAS staining in the oocyte cytoplasm eliminates the possibility of glycogen as a reserve in the oocytes of this species. The chief oocyte reserve appears to be lipid (visible as clear globules in the trichrome-stained sections), as is the rule in the Mollusca (Gallager & Mann 1986, Lucas et al. 1986, Caers et al. 1999, Lu et al. 1999). Large lipid reserves have been reported in the ovaries of both *Haliotis* and *Megathura* genera (Webber 1977).

Although histological examination is a well-established technique for the detailed documentation of reproductive cycles (Webber 1977, Beninger 1987, Barber & Blake 1991), the results of the present study show that this approach, while very useful for elucidating other aspects of the reproductive biology of *M. crenulata*, cannot be used to follow and pinpoint spawning preparedness in this species. However, the eventual rearing of *M. crenulata* will require this information; even more desirable would be a non-destructive technique of monitoring the reproductive status of broodstock. Such biological monitoring of broodstock could lead to increased fertilization success, and hence increased production of adults for pharmacological use.

Several additional aspects of the reproductive biology of *M. crenulata* which could be usefully pursued include the dynamics of gametogenesis (especially the transition from small uncoated oocytes to large coated ones), the buildup of vitteline reserves, the characteristics of gamete storage, and the mechanisms of gametogenetic synchronization. Such information will be most helpful in both the management of wild stocks, and in future aquaculture operations.

MODELING THE GROWTH OF THE CHILEAN LOCO, *CONCHOLEPAS CONCHOLEPAS* (BRUGUIÈRE, 1789) USING A MODIFIED GOMPERTZ-TYPE FUNCTION

LUCIANO RODRÍGUEZ,[1,2]* GIOVANNI DANERI,[2] CRISTIÁN TORRES,[1] MATÍAS LEÓN,[1] AND LEONARDO BRAVO[1]

[1]*Escuela de Pesquerías y Cultivos, Universidad del Mar, Carmen 446, Cerro Placeres, Valparaíso, Chile;* [2]*Centro de Ciencias y Ecología Aplicada (CEA), Universidad del Mar, Carmen 446, Cerro Placeres, Valparaíso, Chile*

ABSTRACT A modified Gompertz-type function was fitted by nonlinear numerical methods to the absolute growth rates(mm/day) of the marine gastropod *Concholepas concholepas*, known in Chile as "loco." The data for this study were obtained from laboratory and field experiments as well as from published and unpublished reports of loco growth. The fit of the modified Gompertz-type function was compared to the fit obtained with the commonly used von Bertalanffy function using the Akaike information criteria corrected by sample size bias (AIC_c). The modified Gompertz function used in this study was $dL/dt = (a_0 L^{a1})*(exp^{-a2t}) + a_3$, where L is the peristomal length (mm), and a_0, a_1, a_2 and a_3 are the parameters of the model. The biological meaning of the constant a_3 of the function is equivalent to the asymptotic growth rate for the species. The von Bertalanffy growth rate equation can be expressed as $dL/dt = -k(L_\infty - L)$. This equation represents a straight line with a negative slope equal to $-k$ and with the y-axis intercept $dL/dt = 0$, providing an estimate of L_∞. The fitted parameters obtained by fitting a modified Gompertz-type of model to the pooled growth rate data were $a_0 = 2.9300e{-}05$, $a_1 = 4.2605$, $a_2 = 0.2011$, and $a_3 = 0.02852$ with a degree of freedom corrected $r^2 = 0.595$. For the von Bertalanffy function the fitted parameters were $k = 5.943e{-}04$ (day^{-1}) and $L_\infty = 150.6$ mm with $r^2 = 0.387$. The $AICc$ of the Gompertz fit was −6,086; whereas, the $AICc$ of the von Bertalanffy fit was −5,611. The smaller AIC_c value −6,086 indicates that the modified Gompertz function provides a better fit to the loco growth rate data. The form of the projected modified Gompertz-type growth curve differs notably from the traditional von Bertalanffy curve for juvenile growth. The modified Gompertz model does not reach an asymptotic growth level, predicting instead infinite growth. This latter property could easily explain reported historical findings of loco individuals measuring over 170 mm in peristomal length.

KEY WORDS: Growth rate, Gompertz model, intertidal gastropods, aquaculture

INTRODUCTION

The loco (*Concholepas concholepas* Bruguière, 1789) is a muricid gastropod endemic to the Southeastern Pacific, found along the coasts of Perú and Chile (Bustos *et al.* 1986). Because of the great economic importance attained by the loco in the past two decades, its natural stocks have been under intense exploitation pressure. This has prompted the Chilean Government to enact legal measures aimed at protecting this species by regulating the capture effort and by establishing a minimum legal size of extraction (100 mm, peristomal length) (Montt *et al.* 1977). The locos are mainly exploited by the artisanal sector, which adds a social dimension to its economic importance. The factors above have made the loco one of the better-studied marine gastropods in Chile, with most of the research effort directed toward commercial farming of this species.

Growth-rate studies of loco juveniles have been carried out in the laboratory (Méndez & Cancino 1992), in suspended lantern nets (Varela & Pérez 1987), and in the field, especially in intertidal rocky shores (Guisado & Castilla 1983, Bustos *et al.* 1985, Bustos et al. 1986, Adlerstein 1986). The early studies of age and growth of loco were initially descriptive and were not used to produce mathematical growth models (Tobella 1975, Lozada *et al.* 1976, Acuña & Stuardo 1979). Later studies were oriented toward satisfying the management requirements of the loco fishery. Initially, several authors applied linear functions to describe the growth of loco juveniles (Guisado & Castilla 1983). More recently, Reyes and Moreno (1990) employed linear and exponential models to describe the growth of juveniles under 10 mm length from the Mehuín marine reserve in the X Region of Chile (Fig. 1). However, the function most widely used to model loco growth and to regulate its fishery is the von Bertalanffy (1957) growth equation (Bustos *et al.*1985, Bustos *et al.* 1986, Adlerstein 1986, Castilla & Jerez 1986, López 1987).

The von Bertalanffy growth equation can be expressed as $dL/dt = -k(L_\infty - L)$. This differential equation represents a straight line with a negative slope equal to $-k$ and with the y-axis intercept $dL/dt = 0$, providing an estimate of L_∞. Use of the von Bertalanffy equation is limited, because often it does not adequately reflect the growth of immature or juvenile individuals. In addition, in its original form, the von Bertalanffy equation does not include the seasonal oscillation of growth, an important factor if the growth of organisms is to be described on short time scales (Pauly & Gaschütz 1979, Gaschütz *et al.* 1980, Akamine 1986, Allison 1994, Askew 1995) and specifically for intertidal gastropods, (Ekaratne & Crisp 1984, Santarelli & Gros 1985, Noda 1991, Shepherd *et al.* 1995).

An alternative to the von Bertalanffy function is the Gompertz function, which in a modified version, has been used to model individual growth rates of juvenile and adult abalones (*Haliotis asinina*) (McNamara & Johnson 1995), pre- and postlarval stages and adult fishes (Smith & Kostlan 1991; Williams & Lowe 1997; Zweiffel & Lasker 1976) and crustaceans (Misra 1957).

In this paper, data from growth experiments of loco individuals grown in the laboratory and in suspended lanterns, as well as data obtained from a wide variety of literature sources, were pooled together employing meta-analysis techniques. The use of meta-analysis makes it possible to integrate and summarize information coming from a wide variety of sources. As applied to stock assessment, meta-analysis involves the compilation of pre-existing

Figure 1. Geographic distribution of *Concholepas concholepas* in Chile and location of study area Quintay Bay, V región.

datasets to determine the values of parameters of models or to develop prior probability distributions of these parameters (Cooper & Hedges 1994, CFSAM 1998). This approach permits a test of the hypothesis that a modified Gompertz equation provides a better model of the loco growth curve than the commonly used von Bertalanffy function. It is hoped that the development of more accurate loco growth models will improve the management of this commercially and socially important marine resource.

MATERIALS AND METHODS

The data used in this study were taken from growth studies of loco juveniles carried out in laboratory conditions and in suspended lanterns anchored in the Quintay Bay (33°11′ S; 71°42′ W), V Region of Chile (Fig. 1). Loco juveniles were collected from the intertidal rocky shore. Individuals were marked with circular plastic tags (2-mm diameter) and the peristomal length (Fig. 2) was measured with a precision caliper (± 0.05-mm).

The laboratory growth experiments of loco juveniles were carried out in two 40-L glass tanks (0.5 × 0.4 × 0.4), using the facilities of the School of Fisheries, Universidad del Mar. Each tank was furnished with independent airflow systems powered by Elite 800 electrical pumps with a 2,100-cc air/min capacity. During the study, the water temperature in the aquarium tanks was 20° C ± 2°C. Growth controls throughout the study were taken on days 19, 34, 55, 69, and 90. Loco individuals grown in laboratory and in culture systems were fed *ad libitum* with a monospecific diet, based on live intertidal mussels, *Perumytilus purpuratus* (Lamarck 1819), one of the main prey items of the locos in their natural environment (Castilla et al. 1979). The initial peristomal length-size range of the locos grown in laboratory conditions was 24 to 64 mm.

The growth experiments in suspended lanterns were carried out in the Quintay Bay during two periods lasting 54 and 140 days, respectively. The loco growth lanterns were especially designed, having a hard plate made of fiberglass that offered an anchor substrate to the locos (Fig. 3). The initial peristomal size range of the loco juveniles grown in lanterns was in the same peristomal size range (24 to 64 mm).

The size increments were calculated using the absolute growth rate, mathematically represented by:

$$\frac{\Delta L}{\Delta t} = \frac{L_f - L_i}{t_f - t_i} \tag{1}$$

where L_f and L_i are the final and initial peristomal lengths and t_f and t_i are the final and initial times corresponding to the aforementioned lengths. The calculated growth rates values were fitted

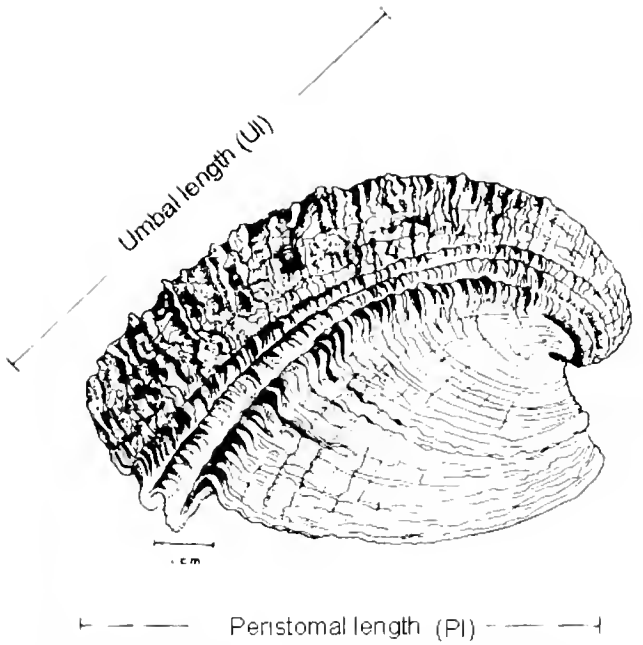

Figure 2. Diagram showing a loco (*Concholepas concholepas*).

to the modified Gompertz and von Bertalanffy functions using the Levemberg – Marquardt algorithm from the Table Curve 4.0 package (SPSS 1998).

The modified Gompertz function is expressed as:

$$\frac{dL}{dt} = (a_0 L^{a1}) * (\exp^{-a_2 L}) + a_3 \qquad (2)$$

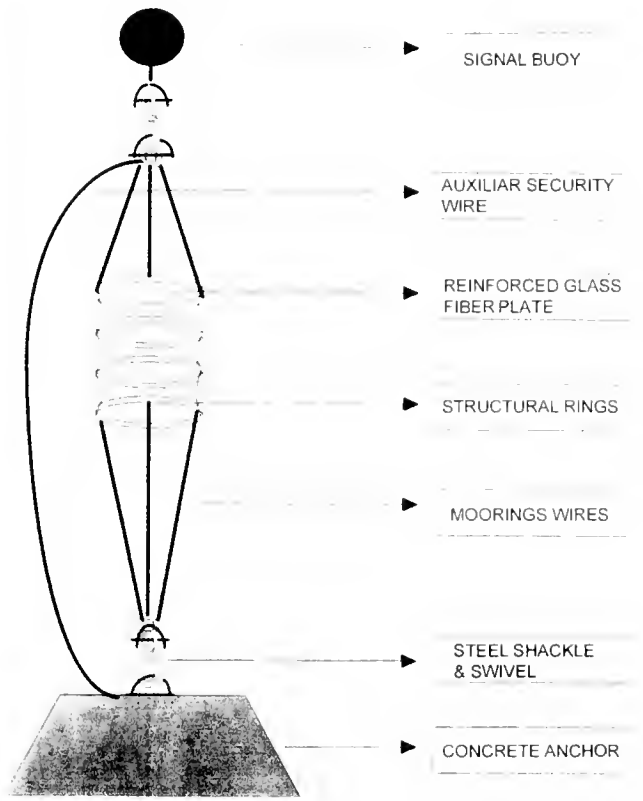

Figure 3. Diagram of the suspended lantern net designed to grow locos in natural conditions.

where L is peristomal length (mm) and, a_0, a_1, a_2, and a_3 are the fitting parameters where a_3 is equivalent to the asymptotic growth rate for the species. The first term of this expression ($a_0 L^{a1}$) is analogous to the power allometric equation proposed by Parker and Larkin (1959); whereas, the second ($exp^{-a2 L}$) is a factor that produces a decreasing growth rate beyond the maximum value of the function. This inflection point is represented by the size of individuals at which sexual maturity is reached.

The von Bertalanffy function is expressed as:

$$\frac{dL}{dt} = -k^*(L_\infty - L) \qquad (3)$$

where L_∞ and k are the asymptotic peristomal length and the curvature parameters, respectively.

The selection of the best-fit growth curve was made based on information theory (Akaike1974, Burham & Anderson 1998). The specific tool used for model comparison and selection was Akaike's information criteria corrected for sample size bias, AIC_C defined as:

$$AIC_C = n^*\log_e(MSE) + 2K + \frac{2K(K+1)}{(n-K-1)} \qquad (4)$$

where *MSE* is the mean square error from the model, n is the number of datapoints, and K is the number of parameters to be estimated. The first term of this expression reflects the lack of fit, the second is a penalty term for complexity or lack of parsimony of the model, and the third term is a correction factor for sample size bias. Lower AIC_C values indicate a better model fit (Burham and Anderson 1998).

If we know the functional relationship between growth rate and length, an individual's body size as a function of age or time frame can be obtained by reorganizing Eq. 2 and integrating:

$$\int_0^t dt = \int_{L_0}^{L_t} \frac{dL}{(a_0 L^{a1}) * (\exp^{-a_1 L}) + a_3} \qquad (5)$$

where L_t is the final peristomal length (mm) of the individual at age or time t, and L_0 is the initial peristomal length (mm) of the individual at the beginning of the experiment or when $t = 0$. Equation 5 cannot be solved analytically; however, a solution can be obtained numerically using a numerical integration subroutine available in any specialized mathematical software package.

Because it may be convenient to use a simpler and more practical method for growth projections in the farming business, we also use a recursive-type approximation based on a discrete time interval Δt, which is mathematically represented as:

$$L_j \approx L_{j-1} + \sum_{i=1}^{30} (a_0 L_i^{a1} * \exp^{-a_2 L_i} + a_3) * \Delta t \qquad (6)$$

where L_j is the peristomal length in the j-th period, and L_{j-1} is the peristomal length in the $(j-1)$-th period. The term between parentheses is the growth rate expressed in mm/day of an individual in the $(j-1)$-th period, which is dependent on length and the discreet increment $L_i = (L_{i-1} + \Delta L_{i-1})$, and Δt is the timestep interval in days. The timestep utilized was one day, and the unit growth period utilized was monthly.

The loco growth data from this study were pooled with published and unpublished loco growth datasets (Table 1). This al-

lowed a substantial increase in the size distribution of the data fitted to the von Bertalanffy and the modified Gompertz growth function.

RESULTS AND DISCUSSION

The average growth rate of loco individuals in the laboratory (0.038 mm/day and standard deviation 0.014 mm/day), was about one-half the average growth rate for individuals grown in suspended lantern nets in the field (0.070 mm/day and standard deviation of 0.027 mm/day). The growth rate ranges observed in the laboratory and in the field are, however, in agreement with growth rates reported for other muricid species by Spight *et al.* (1974). The observed differences between growth rates in the laboratory and suspended lanterns probably reflect better growth rate conditions in the field. The locos grown in suspended lanterns were subjected to lower and more variable changes of ambient temperature (range 10 C –20°C) than the locos grown in the laboratory. Higher temperatures have been associated with higher growth rates in locos grown under laboratory conditions (Méndez & Cancino,1992); therefore, the higher growth rates obtained under colder field conditions would indicate that factors other than temperature should be used to explain the observed growth rate difference between laboratory- and lantern-grown locos. This conclusion must be reached with caution, however, because the results reported by Méndez & Cancino (1992) (Table 1) are for juvenile locos below the 20-mm peristomal size length; whereas, the present study included individuals in the 24 to 64-mm size range. For the same reason, growth rates obtained in the laboratory in this study are not directly comparable to other laboratory studies of

TABLE 2.

Fitted modified Gompertz and von Bertalanffy parameters for loco growth rates.

Function	Parameters	Standard error	*t*-value	AIC_C
Gompertz modified	a_0 = 2.69e-05	1.625e-05	1.654717	−6086.8
	a_1 = 4.094	0.276217	14.82061	
	a_2 = 0.183	0.010620	17.25293	
	a_3 = 0.0281	0.000777	36.00687	
Von Bertalanffy	k = 5.943e-04	2.722d-05	21.82896	−5611.1
	L_∞ = 150.60	3.138003	48.00212	

Note. The *t*-values serve as indicators of the degree of certainty with the parameters are determined. The parameter with the highest *t*-value, in addition to having the greatest contribution to the fit, will also been determined with the greatest level of certainty (SPSS 1998).

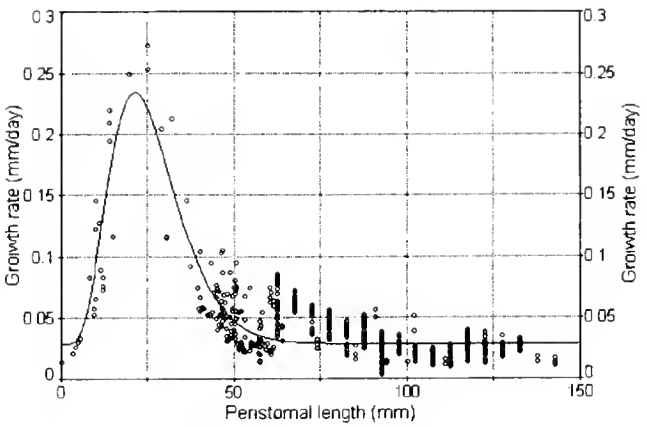

Figure 4. Gompertz curve fit to growth rate of locos.

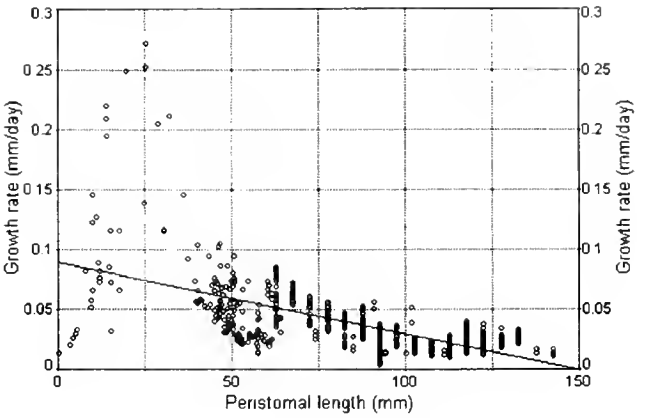

Figure 5. Von Bertalanffy curve fit to growth rate of locos.

loco growth reported by other authors: 0.103 – 0.130 mm/day (Goicochea *et al.* 1991), 0.018–0.058 mm/day (Olivares *et al.* 1990) and 0.046 – 0.075 mm/day (Méndez & Cancino 1992), mainly because these authors worked with loco individuals below the 20-mm size range. Reyes and Moreno (1990) obtained values from 0.022 to 0.043 mm/day for natural loco populations (<20 mm umbal lengths) from the Mehuín marine reserve in the X Region of Chile. This would indicate that environmental pressure can depress the potential juvenile loco growth in the field.

The growth rates reported here are in better agreement with results reported by Rabí and Maraví (1997) for culture experiments in Peru and with growth data reported by Castilla and Jerez (1986) for natural loco population in the V region of Chile. Similar growth rates (0.039–0.073 mm/day) were obtained by Mora (1994) and Rivas (1994) in culture experiments in Caleta Lirquén in the VIII region of Chile (Table 1).

The fitted parameters for the pooled growth rate data obtained during this study and from published and unpublished data for the Gompertz function (Table 2 ; Fig. 4) were a_0 = 2.9300e-05, a_1 = 4.2605, a_2 = 0.2011, and a_3 = 0.02852 with a degree of freedom corrected r^2 = 0.595 and AIC_C = –6,086. For the von Bertalanffy function (Table 2 ; Fig. 5), the fitted parameters were k = 5.943e-04 (day $^{-1}$) and L_∞ = 150.6 with r^2 = 0.387 and AIC_C = –5611. The lower AIC_C value for the modified Gompertz function indicates that this function provides a better fit. Although the corrected r^2 only accounts for 59.5% of the variability of the data, this is, nonetheless, better than the 38.7% obtained with the von Bertalanffy model.

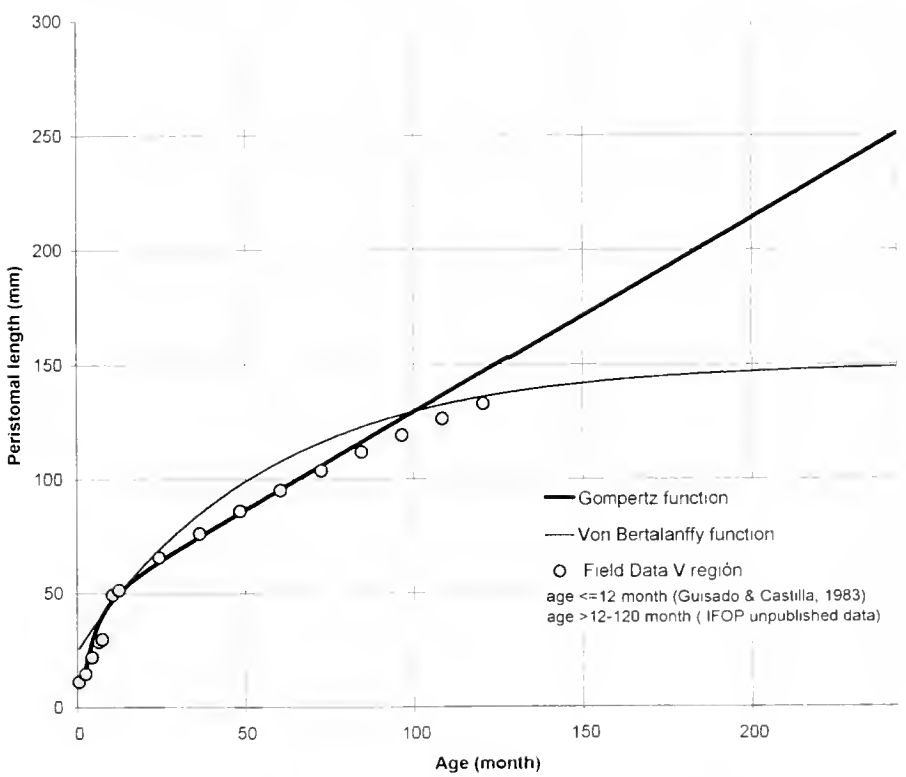

Figure 6. Growth curve of peristomal length (mm) at age (months), for locos measured in natural enviroment. Gompertz function (- - -) and von Bertalanffy function (-.-.-).

The inflection point of the fitted growth-rate curve or point of maximum growth rate (Fig. 4) represents the individual's change of state from a sexually immature to a sexually mature individual. The energy budget of immature individuals is exclusively destined to growth, but when sexual maturation occurs, individuals redirect energy toward the production of gonads, resulting in a marked reduction in growth rates. This inflection point indicates that locos reach sexual maturity at about 25 to 30-mm peristomal length. This is well below the 50-mm minimum size value reported by Ramorino (1979), and it may well reflect a behavioral shift toward earlier time of sexual maturity in the loco population, which, during the last two decades, has been subject to a more intense level of exploitation.

A growth projection of this species was performed as a function of time by using the discrete character expression represented by Eq. 6 and compared to the same projection of the fitted von Bertalanffy growth curve from this study (Fig. 6). For the sake of comparison, the sizes of individuals under a year reported by Guisado and Castilla (1983), and the mean length between one and ten years (IFOP unpublished data) for the Region V are superimposed.

The growth projection using the modified Gompertz function indicates that the legal size of capture of 100-mm peristomal length, should be reached in 66 months. The modified Gompertz-type model does not reach an asymptotic size as predicted by the von Bertalanffy expression. Instead, the projected growth, especially for individuals over a year old, has a resulting curve that is notably similar to the infinite growth pattern described for some other marine invertebrates (Tanaka 1982, Tanaka 1988, Phillips *et al.* 1983, 1992, Ariyama 1993, McNamara & Johnson 1995). This could easily explain historical findings of loco individuals measuring over 170 mm in peristomal length. Furthermore, the fitted von Bertalanffy curve does not adequately describe the juvenile loco growth pattern. Our results indicate that the modified Gompertz equation provides a stronger model of the loco growth curve than the commonly used von Bertalanffy function. Based on these results, we propose that the modified Gompertz equation described in this study should be used routinely in the management models of the commercially and socially important loco species.

UNCOVERING ECONOMIC BENEFITS OF CHIVITA (*MELONGENA MELONGENA* LINNAEUS, 1758 AND *MELONGENA CORONA BISPINOSA* PHILIPPI, 1844)

MICHAEL D. KAPLOWITZ*
Michigan State University, 311A Natural Resources, East Lansing, Michigan 48824

ABSTRACT West Indian crown conch *Melongena melongena* Linnaeus and other crown conch e.g., *Melongena corona* Gmelin have been viewed by most researchers and marine resource beneficiaries as predatory species with little or no value. Focus groups and individual interviews were conducted with local residents as part of the design phase for an economic valuation study of mangrove ecosystems in Yucatán, Mexico. They examined how local inhabitants use, perceive of, and understand ecological services associated with their shared mangrove ecosystem. The data revealed that collection of *Melongena melongena* and *Melongena corona bispinosa* Philippi (collectively called "chivita") has become an increasingly significant component of these communities' economic activity. It was learned that chivita collection is replacing other marine resource-based subsistence strategies in these communities. These findings place *Melongena melongena* and *Melongena corona bispinosa* in a new light.

KEY WORDS: Mangroves, qualitative methods, economic value, Mexico

INTRODUCTION

The West Indian crown conch (*Melongena melongena* Linnaeus, 1758) is generally thought of as a predatory species that preys on other "valuable" species such as the oyster (*Crassostrea virginica*, Gmelin) (Villarreal 1989). The published research on the West Indian crown conch and its close relative the Florida crown conch (*Melongena corona* Gmelin) has centered on the predatory nature and behavior of these species (Bowling 1994, Dalby 1989, Ellison and Farnsworth 1992, Garcia-Cubas 1981, Villarreal 1989). Some of the only reported research on *Melongena corona bispinosa*, Philippi, 1844 appears as part of conference proceedings several years ago and centers on the reproductive life of the conch (Manzano et al. 1998; Zárate and Arana 1998; Zárate et al. 1998). In Mexico and in this paper, the West Indian crown conch (*Melongena melongena L.*), Caracol Negro [Black conch] (*Melongena corona bispinosa*), and the Florida crown conch (*Melongena corona*) are collectively referred to as "chivita" (Secretaria de Medio Ambiente Rucursos Naturales y Pesca [SEMARNAP] 1995). While there have been a few passing references to some economic value associated with chivita, there appear to be no documented studies in the literature on economic, ecological, or social benefits associated with these shellfish.

In several instances, researchers have made reference to some commercial value associated with chivita. Villarreal (1989) makes the passing remark that in Veracruz, Mexico, "fishermen . . . believe that [*Melongena melongena*] should be exterminated. On the other hand, since this snail is of economic importance, its capture is considered more attractive." However, Villarreal Chavez does not support, amplify, or explain what is meant by this. Elsewhere, Solfs-Ramfrez (1994, 20) includes chivitas (*M. melongena* and *M. corona*) as commercially exploitable shellfish species in one of that author's tables on the mollusks of the Yucatán Peninsula. Unfortunately, Solfs-Ramfrez does not refer to chivita in the article's text nor further explain the chivita reference. Most recently, Zetina Zárate et al. (1998), in their introductory remarks on the reproductive cycle of *M. corona bispinosa*, make otherwise unsupported statements to the effect that the collection of chivita is important and subject to increasing collection pressures. As a result of the absence of information on economic benefits associated with chivita collection, this paper provides some useful information on the economic significance of the collection of West Indian conch and Black crown conch (chivita) in coastal communities in northern Yucatán, Mexico.

Hypotheses

Complex environmental and natural resources, such as the Yucatán's mangrove wetlands and coastal resources, represent substantial sources of cultural, intergenerational, environmental, and economic wealth (Aylward and Barbier 1992, Bann 1997, Barbier 1994, Barbier et al. 1997, Carson 1998, Perrings 1995). As part of an effort to identify the range of relevant ecosystem services for a study of the economic value of mangrove ecosystems in northern Yucatán, Mexico, I undertook a series of qualitative inquiries. Two qualitative research methods were used—focus groups[1] and individual interviews.[2] This paper examines research questions concerning the economic significance of chivita collection in two coastal fishing communities bordering Chelém Lagoon near Progresso, Mexico. This paper focuses on how local beneficiaries perceive, use, and value chivita. First, the hypothesis is explored that chivita collection is a positive economic activity for the communities of Chelém and Chuburná. A second hypothesis examined whether there is a significant positive economic benefit associated with chivita collection. It should be noted that findings concerning conflicting management agendas and the relative merit of the use of focus group and individual interview data for resource valuation are presented elsewhere (Kaplowitz and Hoehn 2001, Kaplowitz 1999, Kaplowitz 2000a, Kaplowitz 2000b). This paper briefly describes the research design and locale before discussing the collection method and analysis of data on the economic significance of chivita collection. Finally, the results are

[1]Focus groups are carefully planned discussions designed to learn about subjects' perceptions on a defined area of interest in a permissive, nonthreatening environment. They are conducted by a skilled moderator who follows a discussion guide and involve as few as 2 to as many as 12 informants.

[2]Individual interviews (also called unstructured, exploratory, intensive, in-depth, and depth interviews) are guided conversations whose goal is to elicit from interviewees (also called informants) rich, detailed materials that can be used in qualitative analysis. The interviewer used the same discussion guide as used in focus groups to guide the one-on-one conversations.

discussed before concluding with some observations and implications of the findings.

MATERIALS AND METHODS

Researchers in diverse fields of study regularly use qualitative methods such as, focus groups and individual interviews, as comprehensive research tools and as important components in designing and implementing reliable research studies (Chilton and Hutchinson 1999, Krueger 1994, Morgan 1997, Schwarz 1997, Sudman et al. 1996, Weiss 1994). Qualitative methods for analyzing and managing shellfisheries have been reported previously (Whitlatch and Osman 1994). Individual in-depth interviews are efficient means for collecting information on beneficiaries' use and understanding of mangrove ecosystems at the local level (Kovacs 1999). Furthermore, focus groups and individual interviews have proven to be complementary in identifying conflicting resource agendas (Kaplowitz 1999). They are also useful for learning from local beneficiaries how they use, perceive, and value environmental and natural resources (Kaplowitz and Hoehn 2001, Kaplowitz 2000a, Mandondo 1997). Studies have also shown that resource beneficiaries' ideas about and use of natural resources may differ greatly from those of scientists and so-called experts (Talawar and Rhoades 1998).

Locale and Procedure

The communities of Chelém and Chuburná, Mexico are located along a 15-kilometer stretch of coastal fringe that borders the Gulf of Mexico on one side and Chelém Lagoon on the other. These communities are, respectively, about 3 and 15 kilometers west of the port city of Progresso. The villages are comprised of families that have traditionally relied upon the natural resources of the region, including the mangrove wetland, for their subsistence and livelihood. The inhabitants of Chelém and Chuburná share similar socio-economic characteristics and have roughly 475 and 215 households respectively (Instituto Nacional de Estadfstica Geograffa e Informática [INEGI] 1992). Traditionally, these communities have relied upon a combination of activities for their subsistence and economic gain. They have been able to survive long periods (November to March) of seasonal bad weather "nortes" by developing a multiple use and activity strategy of combining fishing in the sea and lagoons, small scale salt extraction, agriculture, and tourism activities (Paré and Fraga 1994).

A total of 97 year-round residents from the two communities were interviewed in one of 12 focus groups or 19 individual in-depth interviews. The research design allowed for examination of the collected data across interview type, gender, and community. Research assistants canvassed randomly and selected sections of the target communities at staggered times of day to recruit participants. The focus groups were comprised of between four and seven individuals of the same gender from the same village. No respondent or their family members participated in more than one focus group or interview. The focus groups and individual interviews were designed and implemented following the generally accepted practices of Morgan et al (1998), Morgan (1997), Morgan (1996), and Weiss (1994) respectively. A Mexican, professional moderator using a specially prepared discussion guide conducted the focus groups and individual interviews. All focus group and individual interviews were tape-recorded and subsequently transcribed.

Data Analysis

The data analysis allowed me to (1) discover themes, (2) consider the choice and meanings of words, (3) consider the context(s) of data collection, and (4) consider the consistency of responses (Krueger 1994). The analysis did not produce simple counts of things, but rather "fractured" the data and rearranged it into categories that facilitated understanding the data and comparing it within and between categories (Maxwell 1996, Strauss and Corbin 1990). The 12 focus groups and 19 individual interview transcripts resulted in more than 500 pages of text. An iterative, grounded theory approach (Strauss and Corbin 1990) was used to code the transcripts. First, almost every word of a randomly selected subset of transcripts was coded (open coding). Next a set of thematic or summary codes was developed (axial coding). When no new open codes were necessary to code additional transcripts, all of the study's transcripts were axial coded. The final iteration of coding of the text (selective coding) focused on organizing the data into 36 categories relevant to respondents' resource use, value, understanding, perception, and control of the ecosystem.

The reported research here focuses on local beneficiaries' use, perception, and understanding of chivita collection in Chelém Lagoon. The data analysis created and used multiple-response variables to record instances that focus-group discussions and individual interviews raised for discussion matters pertaining to chivita (e.g., shellfish collection, sale of chivita, market price for chivita). For example, the variable "Lagoon fishing" captured and documented a wide range of particular "fishing activity" (e.g., mullet, shrimp, crab, chivita, and other species in the lagoon). Use of such variables accommodated the wide range of the discussion topics as well as allowed the coded transcript data to be subsequently analyzed using statistical software. Furthermore, this approach allowed the focus group and individual interview transcript data to be transformed into variables to test research hypotheses and generate value estimates.

RESULTS

The variable, interview type, records the type of interview (e.g., focus group or individual interview) associated with each case of coded data. Other variables capture those fishery services raised by respondents during the focus groups and individual interviews. Table 1 illustrates the four primary fishery services associated by local beneficiaries with the lagoon and that emerged from the focus group and individual interview data. Table 1 also presents some representative references as well as the percentage of focus group and individual interview sessions that raised for discussion each fishery service. As can be seen, participants, in general discussions of the region, the ecosystem, and what they do, talked about "fishing in the lagoon" quite frequently. Interestingly, participants discussed chivita collection most frequently and in almost all of the sessions. The other significant "fishing activities" associated with the lagoon and raised by participants include the collection of crab as bait for use during the limited octopus (*Octopus maya* and *Octopus vulgaris*) fishing season and the increasingly infrequent collection of shrimp in the lagoon. These results are especially noteworthy when one considers that local researchers, regional coastal resource managers, environmentalists, and government officials failed to mention chivita collection as a local

TABLE 1.

Fishery service variables.

Topic variable	Example	% sessions raising topic
Chivita	*Melongena melongena; Melongena corona bispinosa;* used for food and commerce	97
Lagoon fishing	we fish in lagoon; people come to fish in wetland; some use their nets day & night at lagoon entrance	91
Crab	collected as bait; frozen for use during two month octopus season	61

activity or an ecosystem service in more than 12 interviews conducted prior to the focus groups and individual interviews.

As the data illustrate, the qualitative research revealed information about the use and understanding of the complex coastal ecosystem as a fishery. The qualitative data revealed the importance of chivita collection to the subsistence of the local inhabitants of the Chelém Lagoon region.

Focus groups and qualitative interviews can produce opinion and economic data that is consistent with traditional survey research data (Reynolds and Johnson 1978, Vaughn et al. 1996). The data were also coded to capture respondents'comments on catch rates and prices associated with the collection of chivita. As Table 2 illustrates, respondents reported a range of chivita collection rates and market prices. Some participants mentioned collection rates per working day ranging from as few as 0.5 kilograms to as many as 4 kilograms. Many respondents spoke about once being able to easily collect more than 10 kilograms per day during good times. During the sessions, respondents also volunteered a range of prices being paid for chivita by brokers or middlemen in the region. As Table 2 shows, the average price per kilogram was about 8 pesos or approximately $1.13. The brokers, in turn, transported and sold the chivita to hotels and restaurants in the tourist trade for use as appetizers and table snacks.

It must be pointed out that this area enjoys a potentially lucrative octopus fishing season from mid-August through late-November. While there are reports that chivita and other lagoon species are collected during Octopus season, many men reported focusing on the octopus season, if able. This is not true for the women of the area who reported collecting chivita to sustain their families throughout the year, especially while their husbands go to fish in the sea. As Figure 1 illustrates, the communities of Chelém and Chuburná derive significant economic benefits from their extractive use of chivita from the Chelém Lagoon. Using the median reported catch rates and the median reported market price, it is estimated that chivita collection represents approximately $230,000 to $350,000 dollars of income to these communities. That is, a family relying on the lagoon for chivita collection year-round can generate about $580 dollars annually, or about $390 dollars from chivita if they devote four months completely to octopus fishing. These findings are especially significant when compared to the Mexican minimum wage of 14 pesos ($2) per day paid at factories in the region, when there is available work.

Chivita collection reports

Variable	Low	High	Mean
Catch rate (kg/day)	0.5	4	1.8
Price* (Pesos/kg)	5	10	7.9

* Exchange rate at the time about 7 pesos to $1 US.

DISCUSSION

As the foregoing analysis demonstrates, chivita collection is the most significant economic activity associated with the lagoon fishery for the communities of Chelém and Chuburná. While the participants mentioned the collection of small crabs, it turns out that the unidentified species collected is too small to support human subsistence and is used as bait for the brief octopus (*Octopus maya* and *Octopus vulgaris*) season in the nearby Gulf of Mexico. The existing economic difficulties facing these communities and Mexico as a whole repeatedly came to light during the focus groups and individual interviews. The sessions were replete with discussions of the difficulty in providing for one's family. Increasing commercial fishing pressure by trawlers in the offshore and near-shore fisheries of the Gulf of Mexico is reported to have decimated the once rich coastal fishing resource. Local beneficiaries have responded by increasing their reliance upon the lagoon and its mangrove ecosystem for subsistence.

The focus groups and individual interviews left no doubt that lagoon fishing for chivita is of utmost importance to local people. The collection of chivita from the muddy bottom of the Chelém Lagoon has become the predominant subsistence strategy for the regions' communities. Repeatedly, I was told of mothers placing their small children on planks of wood so that they could attend to them while digging for chivita in the lagoon's muddy bottom. Chivita collection has replaced other more conventional lagoon fishing and the collection of crabs as the key lagoon fishery service. When the Gulf of Mexico's fishery was thriving, there were reports that local beneficiaries were using the lagoon only as a place to collect their bait. However, the decline of the near-shore fishery has resulted in changes.

While shrimp collection in the lagoon was mentioned in the sessions, it occurs only occasionally. According to participants, the recent construction of a duck habitat restoration dike by Ducks Unlimited and Mexican Navy activities, have caused drastic curtailment of the once annual or biannual inundation of shrimp in the lagoon. It is reported that these projects have stopped the circular flow of seawater through the lagoon that resulted after Hurricane Gilbert. Another lagoon-based activity that has been curtailed is salt collection. At one time, individuals in the region could construct salt ponds; flood them with seawater, allow the water to evaporate and then collect and sell crystallized sea salt. However, the area's lucrative salt mining business has been defunct for years. This change followed the flooding and ipso facto enlarging of Chelém Lagoon when the Mexican government dredged and constructed a safe harbor and naval station in the lagoon in the late 1960s and early 1970s (Paré and Fraga, 1994).

It seems that virtually every family in the two communities, at one time or another has adopted chivita collection as part of its subsistence survival strategy. Furthermore, it is common for al-

SEASONAL CHIVITA COLLECTION

Figure 1. Benefit of chivita collection.

most everyone in the area to refer to himself or herself as a "pescador" (fisherman) despite the fact that many provide for themselves and their families by working in nearby factories or doing construction work. Individuals when speaking about lagoon fishing perceive themselves as "fisherpeople", and it was learned repeatedly during the sessions that respondents include chivita collection, crab and shrimp collection together with line and net fishing for other species. What makes this especially interesting, is that researchers from nearby Mérida working on coastal zone management in the region were surprised to learn of the extent to which the respondents relied upon chivita collection. It was their belief that chivita was a minor component of residents' subsistence strategy and that near-shore fishing in the gulf was the predominant occupation in the area.

In the words of one respondent:

> We used to make a living fishing in the sea . . . Now you can't make a profit more than 2 to 3 months from fishing in the sea . . . The same problem is also happening in the lagoon, it used to be that you could take all the crab you wanted. Now only the small ones are around . . . While some try to work elsewhere, people sustain their families with chivita from the wetland (Transcript 18).

CONCLUSION

This study demonstrates that chivita collection is not only a benefit to these communities but it is a significant source of their subsistence activity. The data show the value of using individual interviews and focus groups to learn from local beneficiaries about their ecosystem and natural resource use. The finding that the West Indian crown conch (*Melongena melongena* L.), *Caracol Negro* [Black conch] (*Melongena corona bispinosa*), and the Florida crown conch (*Melongena corona*) are significant sources of subsistence and income, place these species in a new economic light. For the people of Chelém Lagoon, these species are welcome visitors not predators.

YELLOW AND BROWN SHELL COLOR MORPHS OF *CORBICULA FLUMINEA* (BIVALVIA: CORBICULIDAE) FROM SICHUAN PROVINCE, CHINA, ARE TRIPLOIDS AND TETRAPLOIDS

ANDONG QIU,[1] ANJING SHI,[1] AND AKIRA KOMARU[2,*]

[1]*Sichuan University, Department of Biology, Chengdu 610064 Sichuan, People's Republic of China;*
[2]*Mie University, Faculty of Bioresources, Tsu-city, Mie, 514-8507 Japan*

ABSTRACT Yellow and brown shell color morphs were distinguished in samples of *Corbicula fluminea* collected from Anyue County, Sichuan Province, China. Shells of yellow morphs are straw yellow externally and white internally, while those of brown morphs are dark brown and purple, respectively. Karyological and DNA microfluorometric analyses revealed that yellow and brown morphs are triploid and tetraploid, respectively. Both are simultaneous hermaphrodites with non-reductional and biflagellate spermatozoa and brood their larvae in the inner demibranchs like diploid *C. fluminea* in Taiwan and Japan. These reproductive characteristics are similar to triploid *Corbicula leana* in Japan, which is self-fertilizing. These results suggest that *Corbicula fluminea* at different ploidy levels may also reproduce by self-fertilization.

KEY WORDS: *Corbicula fluminea*, triploid, tetraploid, karyotype, DNA microfluorometry

INTRODUCTION

The freshwater bivalves, *Corbicula leana* (Müller) and *Corbicula fluminea* (Müller), are hermaphroditic and brood their larvae (Miyazaki 1936, Kraemer and Galloway 1986). In both species, one individual can reproduce by self-fertilization (Ikematsu and Yamane 1977, Kraemer 1978). Both species show little allozyme polymorphism (Hillis and Patton 1981, Sakai et al. 1994). This monogenic condition has been explained as self-fertilization (Mcleod and Sailstad 1980) or gynogenetic development (Okamoto and Arimoto 1986).

C. leana in Japan is triploid and *C. fluminea* in Taiwan and Japan is diploid, both species producing non-reductional spermatozoa (Okamoto and Arimoto 1986, Komaru et al. 1997). We have also produced cytological evidence of spontaneous androgenetic development in *C. leana* (Komaru et al. 1998). These similar reproductive characters suggest that diploid *C. fluminea* may also reproduce by self-fertilization.

In this study, we identified two obviously different shell color morphs of *C. fluminea* and studied their chromosomes, spermatozoa, and somatic cell DNA to identify genetic differences between and reproductive modes in them.

MATERIALS AND METHODS

The Samples

The *Corbicula fluminea* (Müller) samples were collected from a stream in Anyue County, Sichuan Province, People's Republic of China, in September 1997. The two color morphs were collected at the same sampling site. The samples were transferred to Sichuan University, Chengdu, Sichuan, China and the National Research Institute of Aquaculture, Nansei, Mie, Japan, and kept in laboratory aquaria.

Chromosomes

The samples were transferred to freshwater containing 0.002% colchicine for 4–5 hours. The gills and gonads were then dissected out and hypotonically treated with distilled water for 30 min and fixed in Carnoy's fixative. Small pieces of gill or gonad were minced in 50% acetic acid and isolated cells were placed on slides, air-dried, and stained with 2% Giemsa in phosphate buffer (pH = 7.2) (Okamoto and Arimoto 1986). For chromosome classification and karyotyping, metaphase chromosomes were measured and paired on the basis of relative length and centromeric index.

DNA Microfluorometry

Spermatozoa and somatic cells from the mantle were isolated in distilled water, placed on slides, air-dried, and fixed with 70% ethanol. The slides were then stained with a DAPI staining solution. Relative DNA content was estimated by microfluorometry after DAPI staining (Komaru et al. 1988).

Light Microscopy

Gonads and gills were fixed with 10% formaldehyde and processed for paraffin sectioning. Slides were stained with Mayer's hemalum and eosin.

Spermatozoa Measurement

Spermatozoa were isolated from the gonads in freshwater and observed by phase contrast microscopy. The lengths of the sperm head and flagella were estimated using an ocular micrometer.

RESULTS

Shell Color and Size

Figure 1 shows the two shell color morphs (yellow and brown) of *Corbicula fluminea* from Anyue County. Externally, the shell surface of the brown morph is dark brown (Fig. 1A), and its inner surface is deep purple along the ventral margin, but rather white from the pallial line to the umbo (Fig. 1B). The external surface of the yellow morph is straw-colored (Fig. 1A) while the inner surface is white (Fig. 1B). This form is also characterized by purple flashes along the anterior and posterior lateral teeth.

Shell lengths (SL), heights (SH), and widths (SW) were not significantly different between the yellow and brown morphs, but the three ratios of SW/SL, SW/SH, and SW/ (SL+SH+SW) are significantly larger in the yellow than in the brown morph, whereas the ratio of SH/SL in both morphs is similar (Table 1).

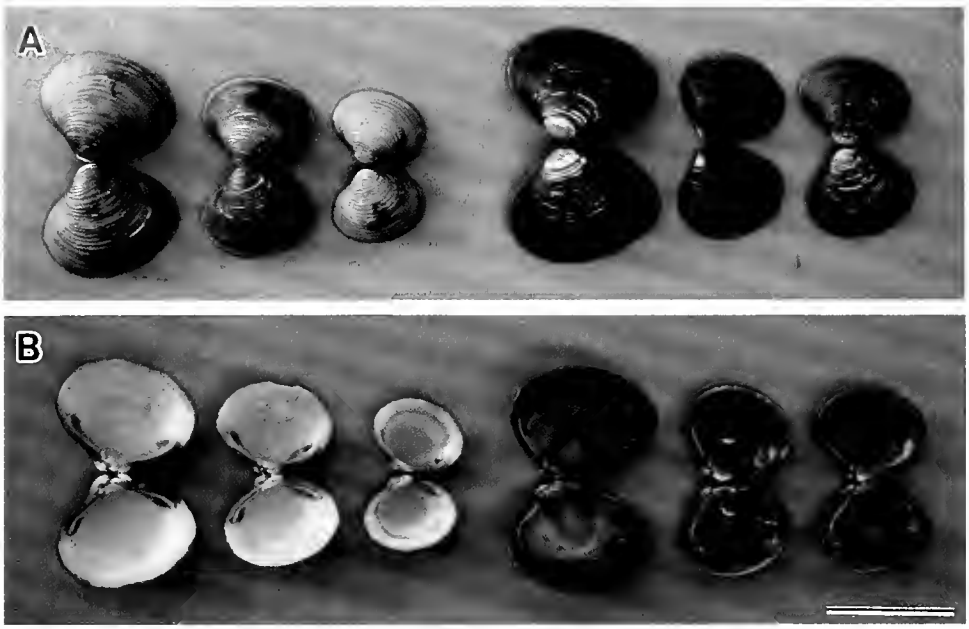

Figure 1. External (A) and internal (B) views of the shells of yellow (left) and brown (right) morphs of *Corbicula fluminea* collected from Anyue County, PRC.

Chromosomes and Relative DNA Content of Somatic Cells

Chromosome numbers of the yellow morph were 54 in the gills (Fig. 2A) and 18 in the gonads (Fig. 2B), and 72 in the gills of the brown morph (Fig. 2C). Eight well-spread mitotic metaphases of the yellow morph and seven of the brown were measured and karyotyped. Figure 3 shows the karyotype taken from one metaphase of the yellow morph containing 18 triplets arranged on the basis of shared relative lengths and centromeric indices. It consists of 2 metacentrics, 13 submetacentrics (including 3 submetacentrics-metacentrics and 6 submetacentrics-subtelocentrics), and 3 subtelocentrics (Table 2). Figure 4 shows the karyotype of the brown morph. It contains 18 quadraplets, consisting of 2 metacentrics, 13 subcentrics (including 3 submetacentrics-metacentrics and 6 submetacentrics-subtelocentrics), and 3 subtelocentrics (including 2 subtelocentrics-submetacentrics) (Table 3). The meiotic chromosomes of the yellow morph have triplet-like chromosomes and an incomplete synapsis of homologous chromosomes was observed (Fig. 2B). Meiotic chromosomes could not be observed, however, in any studied individuals of the brown morph.

The relative DNA content of the yellow morph was almost the same as that of the triploid *C. leana* collected from Mie Prefecture, Japan, whereas that of the brown morph was about 1.3 times that of triploid *C. leana* (Table 4).

DNA Content of Sperm and Somatic Cells

As shown by DNA microfluorometry of the spermatozoa and somatic cells (Table 5), the relative DNA content of the former was almost identical to that of the latter. Seven yellow morph and eight brown morph individuals all produced spermatozoa with a DNA content similar to that of their own somatic cells.

Spermatozoa Measurements

The sperm heads of both *C. fluminea* morphs are slightly curved and elongated and both have two flagella. The length of the brown morph spermatozoa is significantly longer than that of the yellow. The sperm head size was 20.3 ± 1.0 μm (n = 10) for the yellow morph and 24.0 ± 0.5 μm (n = 10) for the brown morph. Flagella length was 46.2 ± 1.5 μm (n = 10) in the yellow morph and 49.5 ± 1.9 μm (n = 10) in the brown one.

Gonad and Larval Incubation

Gonad and gill sections of 14 yellow and 12 brown morphs were examined. All individuals were simultaneous hermaphrodites. Three of the 14 yellow morph individuals and four of the 12 brown morph were brooding larvae in their inner demibranchs.

DISCUSSION

C. fluminea from Japan and Taiwan have been reported to be hermaphroditic and diploid with $2n = 36$ in the gills and 18 bivalents in the gonads (Komaru et al. 1997). In the present study, yellow and brown color morphs of *C. fluminea* were discovered in Anyue County, Sichuan Province, China, where they are sympatric. According to our karyological and DNA content analyses of these two morphs of *C. fluminea*, the yellow one is triploid with $3n = 54$ in the gill tissues, which can be classified into 18 triplets on the basis of their relative lengths and centromeric indices, and with 18 trivalents in the gonads. The brown morph is tetraploid with $4n = 72$ in the gill tissues, which can be classified into 18 tetraplets.

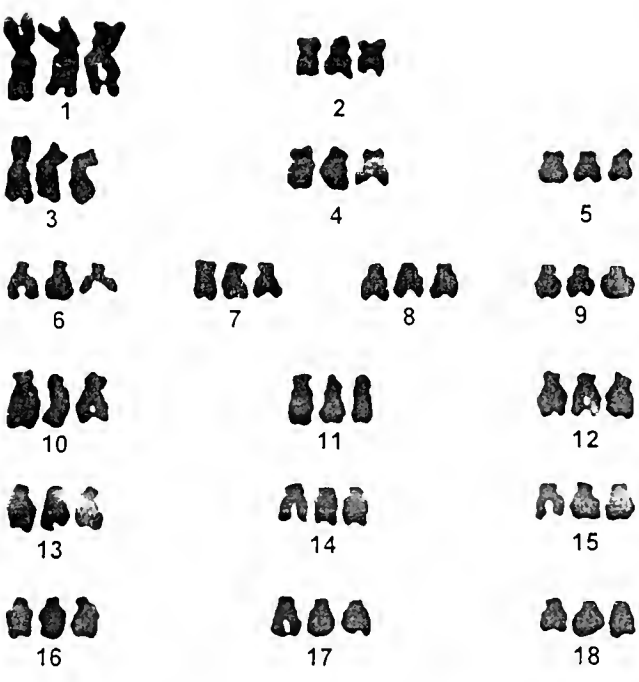

Figure 3. Karyotypes taken from yellow ($3n = 54$) morph of *C. fluminea* metaphases. Scale bar = 5 μm.

A comparison of karyotypes from triploid and tetraploid *C. fluminea* shows that they have a similar formula containing 2 metacentrics, 13 submetacentrics, and 3 subtelocentrics. This implies that they may have the same origin. However, there are also some differences between the karyotypes, so that the No.2 chromosomes of both the triploid and tetraploid had submetacentrics of different relative lengths. These differences indicate that they may have different genetic properties.

The shell color of *C. fluminea* is highly polymorphic (Morton 1987, Chen et al. 1995). Britton and Morton (1986) also identified two different color morphs of *C. fluminea* in USA with significantly different mean shell dimension ratios, and suggested that such polymorphism in shell color and shell size were the result of environmental induction. Morton (1987) identified the same two morphs in Hong Kong and Tsoi et al. (1991) showed there was no genetic differentiation between the two morphs by allozyme analysis. However, triploid and tetraploid *C. fluminea* with different shell colors and sizes in Anyue County are possibly sympatric, which indicate that these distinct differences in the two shell color morphs may be mainly derived from their different genetic constitutions. Physiological studies should be implemented to determine the fitness of both morphs and the significance of the polyploidy.

Triploid and tetraploid *C. fluminea* are hermaphrodites and brood their larvae in the inner demibranchs. The meiotic chromosomes comprise 18 trivalents with an incomplete synapsis of homologous chromosomes in the gonads of triploid *C. fluminea*. These could not be observed in tetraploid *C. fluminea*. These results imply that the triploid *C. fluminea* cannot carry out normal meiosis as in the triploid *C. leana*, and tetraploid *C. fluminea* fail to achieve meiosis. DNA microfluorometry of spermatozoa and somatic cells of the triploid and tetraploid *C. fluminea* showed that they all produce non-reductional and biflagellate spermatozoa similar to *C. leana* in Japan and *C. fluminea* in Taiwan and Japan (Komaru et al. 1997). These results indicate that these polyploids can reproduce in ways different from the normal sexual method. It has been reported that triploid *C. leana* in Japan reproduces by androgenesis which Komaru et al. (1998) cytologically confirmed. In androgenesis, all maternal chromosomes were expelled as polar bodies at the first division after self-fertilizaton, which results in the forming of only one male pronucleus from the spermatozoa but no female pronucleus. Therefore, only the chromosomes deriving from the male pronucleus formed the mitotic chromosomes for the first zygotic cleavage. Diploid (Komaru et al. 1997), triploid, and tetraploid *C. fluminea* have the same reproductive characters as *C. leana*, i.e., hermaphroditic, brooding, and the production of non-reductional spermatozoa. It is possible that *C. fluminea* with different ploidies may also reproduce by androgenesis and be fertilized by autosperm as in *C. leana*.

In the animal kingdom, polyploids are rather rare, as compared with plants. Animals reproducing by parthenogenesis are sometimes polyploid (Hughes 1989). Three different ploidy levels have been known in *Corbicula* up to now. How did they evolve from an ancestral species? We have shown that diploid and triploid *Corbicula* produce non-reductional spermatozoa (Komaru et al. 1997). These data suggest that diploid androgenetic individuals may evolve from a diploid ancestral population with normal meiosis. After androgenesis arose in an ancestral population, mutations for

polyploidy occurred. Lokki (1976) pointed out that in parthenogenetic animals, polyploidy would help to maintain functional loci when mutant alleles are accumulating. This could explain polyploidy in *Corbicula*. It is likely that the triploids and tetraploids in *Corbicula* have arisen from diploids. To increase the ploidy, we assume two possible androgenetic events in *Corbicula*: either (1), production of spermatozoa with increased ploidy levels derived from meiotic failure during spermatogenesis or (2), incomplete polar body formation, i.e., one or two maternal chromosome sets were not extruded and participate in pronucleus formation.

The taxonomy of *Corbicula* has problems (Morton 1986) because the genus contains species and populations that can repro-

duce by self-fertilization and androgenesis. The taxonomy of *Corbicula* should, thus, be determined on the basis of not only shell morphology but also genetic and ecological information. The key to *Corbicula* taxonomy is how species and populations reproduce and how they evolved from an ancestral diploid species. Further studies on the genetic differences and reproductive modes of both morphs of *Corbicula fluminea* are required to identify the evolutionary significance of androgenesis and polyploidy.

Interestingly, there are a few brown individuals with almost the same DNA content as yellow ones, such as B-2 and B-8 in Table 5. It is unknown whether they belong to another polymorphic type of *C. fluminea*, but it is worth studying further. Maybe the genetic polymorphism of *C. fluminea* is much more intricate than what we know until now.

LACK OF SURFACE-ASSOCIATED MICROORGANISMS IN A MIXED SPECIES COMMUNITY OF FRESHWATER UNIONIDAE†

S. J. NICHOLS,[1]* J. ALLEN,[1] G. WALKER,[2] M. YOKOYAMA,[3] AND D. GARLING[3]

[1]U.S. Geological Survey, 1451 Green Rd. Ann Arbor, Michigan 48105; [2]Eastern Michigan University, Ypsilanti, Michigan 48197; [3]Michigan State University, East Lansing, Michigan 48824

ABSTRACT To determine whether unionids contain surface-attached endosymbiotic bacteria, ciliates, or fungi, we used scanning electron microscopy to examine the epithelial surface of various organs within the digestive system and mantle cavity of temperate river and lake unionids on a seasonal basis. We also cultured material removed from the lumen of these same organs and from the mantle cavity to detect cellobiose-, cellulose- and chitin- degrading microbes. No true endosymbiotic fauna were observed attached to the surface of the digestive or mantle tissues of any species of unionid. Microbial growth on cellulose or chitin bacteriological media varied by season and habitat, but not by unionid species or source of the isolate. Lake unionids did not contain microbes capable of digesting cellulose or chitin, whereas unionids from the river site did in March and August, but not in December. Since these cultured cellulose- and chitin-degrading bacteria were never found attached to any unionid tissues, they appeared to be transient forms, not true endosymbionts. Microbes capable of digesting cellobiose were found in every unionid collected in all seasons and habitats, but again, no microbes were directly observed attached to unionid tissues. If unionids, like most other invertebrates, lack digestive enzymes required to initiate primary bond breakage, then the lack of cellulolytic and chitinolytic endosymbionts would affect the ability to utilize cellulose or chitin foods. Thus, in captivity dry feeds based on corn, soybeans, or nauplii should be pre-digested to ensure maximum absorption of nutrients by unionids. The lack of cellulolytic or chitinolytic endosymbionts should not affect relocation success, though the seasonal role of transient microbes in unionid nutrition requires further investigation.

KEY WORDS: gut microflora, endemic microbes, Unionidae

INTRODUCTION

Freshwater unionids in North America are being extirpated at alarming rates due to factors such as habitat degradation and competition from the exotic zebra mussel (*Dreissena polymorpha* Pallas) (Williams et al. 1993). At this time, conservation efforts for adult unionids include relocation into new habitats and intensive aquaculture, but mortality rates have been high with most adults surviving less than three years (Cope & Waller 1995; Lellis and Johnson 1998; Gatenby et al. 1999). Although these high mortality rates are undoubtedly due to a host of different factors, one problem area has been identification of dietary requirements. Little information exists on dietary preferences and required nutrients necessary for formulating a captive diet, and evaluating food resources in new habitats or refugia. The few dietary studies in natural habitats have shown that unionids ingest a wide variety of potential food items including algae, detritus, fungus, rotifers, and zooplankton, with detritus as the dominant component in both the mantle cavity and gut lumen (Lefevre & Curtis 1910; Jiffry 1984; McMahon 1991; Nichols & Garling 2000).

The ingestion of large amounts of detritus implies that detritus is actively selected and thus may play a significant dietary role. This role is not easy to characterize as detritus in aquatic systems represents a complex matrix often containing cellulose from aquatic and terrestrial sources, chitin from fungus, rotifers, and zooplankton, and which has in turn been colonized by bacterial, fungal, and protistan fauna. Thus, ingested detritus could function merely as a substrate for the preferred food item, the associated epiorganisms, or could function as a direct source of nutrients obtained from cellulose or chitin degradation. One complicating factor is that cellulose and chitin are highly complex polysaccharides that require specific enzymes to initiate primary bond breakage. Such primary enzymes are rarely produced endogenously in aquatic invertebrates, and are recorded for very few marine bivalves, although cellulases in general have been detected in both marine and freshwater mollusks. In unionids, the concentration of cellulases present has actually proven to be a successful technique for assessing the health status of the animal (Haag et al. 1993; Farris et al. 1994). However, these cellulase concentrations were obtained from total animal bioassays, from unionids freshly removed from the field, and were not further identified to type. It has not been determined if primary cellulases were present, and if so, whether they were produced endogenously by the unionid, or exogenously by the microbial community associated with ingested food items. Furthermore, chitinases of any type have not yet been reported for either freshwater or marine bivalves.

Most aquatic animals that feed directly on detrital cellulose access the necessary primary cellulases through a symbiotic relationship with some type of bacteria/microbe, and contain recognizable endosymbiotic fauna somewhere in their digestive tracts (black fly larvae, Taylor et al. 1995; crane fly larvae, Klug & Kotarski 1980; mullet, Mountfort & Rhodes 1991). Microbial and endosymbiont/nutritional relationships among bivalves are far more complex than those reported for other aquatic invertebrates and often vary by species as well as by location. True endosymbiotic relationships range from the consistent obligate communities of microbes directly buried within gill tissues of deep-sea hydrothermal vent bivalves (Wood & Kelly 1989), to spirochaetes merely attached to the outside epithelial layer of digestive tissue or to the crystalline style (Bernard 1970; Conway & Capuzzo 1989; Prieur et al. 1990). Geographical variability is common, with endosymbionts existing inside some species at some locations, but not in others (Bernard 1970), while some marine bivalves never exhibit endosymbiotic relationships (Garland et al. 1982). Studies on freshwater bivalve- microbial relationships are very limited (Starliper et al. 1997) and have focused mainly on bacterial communities found in the gut lumen or passing through the intestinal tract. As in marine bivalves (Prieur et al. 1990; Harris et al. 1998),

bacterial communities passing through the gut of freshwater unionids usually differ in species composition from those found in the surrounding water column, reflecting selective predation and subsequent enhancement of bacteria species not directly consumed. However, these are not necessarily residential, or endosymbiotic, populations.

The objective of our study was to determine if certain unionid species contained endosymbiotic microflora that might aid in the digestion of dietary materials such as cellulose and chitin, and if present, did this flora vary by location, season, or species of unionid.

MATERIALS AND METHODS

Study Sites and Unionids

The unionids used in this survey were collected from three sites in southeast Michigan, U.S.A.: the Huron River, Four Mile Lake, and Vineyard Lake. The Huron River is a regulated stream, consisting of a series of impoundments connected by free-flowing stretches of river. Our study area focused on the middle section of the river, where the water is shallow (1 m deep), with an average water velocity of 0.5 m/sec and heavy canopy cover dominated by deciduous trees (Livingston Co., 42°25′41″N, 83°54′40″W). A total of 17 unionid species occur in this river. Four were selected for analysis: *Lampsilis ventricosa* Barnes, *L. siliquoidea* Barnes, *Ptychobranchus fasciolaris* Rafinesque, and *Pyganodon grandis* Say. Four Mile Lake is a 25 hectare lake once used as a marl mining site (Washtenaw Co., 42°20′16″N, 83°58′14″W). Except for the marl pit, the lake is shallow, <2 m deep, with no current flow, and a soft substrate covered with *Chara* spp. Canopy cover is lacking, although some wetland vegetation occurs at the edges of the lake. Only one species, *P. grandis*, regularly occurs in this lake. Vineyard Lake is only 12 hectares is size, is 6.5 m deep, and is sur-

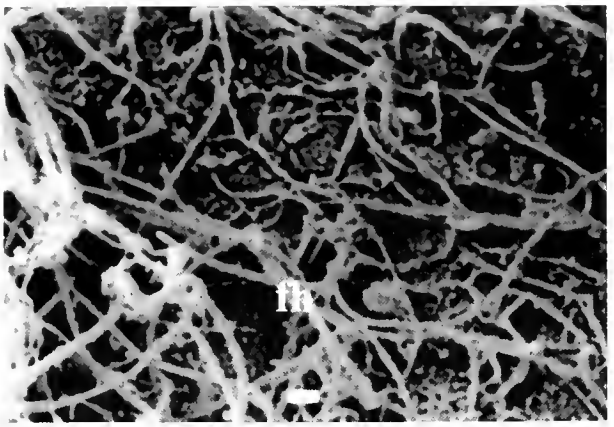

Figure 2. Scanning electron micrograph of fungal hyphae (fh) found growing on the mantle tissue of a single specimen of *Lampsilis siliquoidea* collected from the Huron River in August. Scale bar = 1μm.

rounded by subdivisions (Jackson Co., 42°04′57″N, 84°12′35″W). Only one species, *Elliptio dilatata* Rafinesque, was observed in this lake.

Examination for Surface-Attached Microbes

Sampling for unionids occurred in March, August, and December, and 4 individuals of each species were collected from the Huron River (four species), Four Mile Lake (one species), and Vineyard Lake (one species) (total $n = 24$ unionid specimens for each month for all three sampling locations). Unionids were placed in damp mesh bags in a cooler, and transported to the laboratory. The shell exterior of each unionid was then scrubbed with a brush to remove external flora, rinsed in distilled water, followed by a 10% acetic acid rinse, a second distilled water rinse, and then the shell was pried open. The mantle cavity was rinsed for 3–5 minutes with distilled water and all the rinse water and flushed material was saved. The foot, gills, labial palps, siphons from the mantle cavity, stomach, digestive gland, style sac, style, and fore-mid-hind sections of the intestinal tract were excised and processed for scanning electron microscopy (SEM). Distilled water used to rinse and flush contents from the lumen of each part of the digestive tract with the contents from each organ, as well as the material rinsed from the mantle cavity, were saved separately for culture on bacteriological media.

For scanning electron microscopy (SEM), the separate organs and tissues removed from each unionid were immersed in 10% neutral buffered formalin (primary fixation). After the tissue firmed, serial sections of approximately 1 mm were taken using a scalpel. The tissue was then isolated if needed, trimmed, and washed three times for 20 minutes each in cacodylate-HCl buffer at a pH of 7.2. Secondary fixation involved immersion in 1% cacodylate-HCl buffered osmium tetroxide for one hour. Samples were then dehydrated in a graded alcohol series: 50% (15 min), 65% (15 min), 75% (15 min), 85% (15 min), 95% (15 min), 100% (3 changes 15 min each). Tissues were then critical point dried in CO_2 transition fluid, mounted on 2.5 cm stubs, sputter coated with gold, and examined under a scanning electron microscope.

Microbial Growth on Bacteriological Media

The contents and rinse water were removed from seven areas within each unionid: mantle cavity, stomach, digestive gland, style sac, fore-, mid-, and hind gut. These samples from each of the four individual animals of a particular species collected at each locality were pooled and then used to inoculate three standard enrichment broths, cellulose (carboxymethylcellulose), chitin, or cellobiose. The same amount of inoculant (about 0.10 cc), was removed from each well-stirred pooled sample and placed into a test tube containing cellulose, chitin, or cellobiose with two duplicate sets made (7 internal sources of the inoculant × 2 replicates × 3 media types = 42 total samples per sampling date). This yielded a total of 168 samples for all species in the Huron River each sampling date, and 42 for Vineyard and Four Mile lakes since each had one unionid species present. The duplicate samples for each species and site were randomly split into two groups (3 types of culture media from 7 tissue locations listed above) and then placed in anaerobic or aerobic conditions at room temperature (24°C) using techniques described in Bryant and Burkey (1953, substitute chitin for cellobiose), Bryant (1972), and Hungate (1950). Anaerobic conditions were maintained under a gas phase of 100% CO_2 without agitation. Culture tubes were examined for the presence of fermentation end products (gas production) and media degradation (clouding of media and breakdown of larger chitin particles) after 12, 24, 48, 72, 96, and 120 hours.

RESULTS

Examination for Surface-Attached Microbes

Examination of tissues using the scanning electron microscope showed no attached bacteria, fungi, microciliates, or other types of

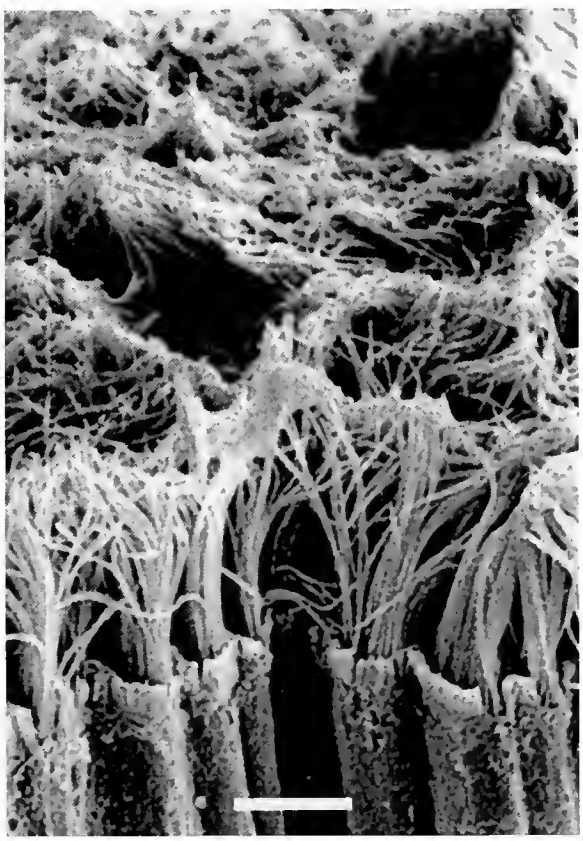

Figure 3. Scanning electron micrograph of unionid intestinal tract showing ciliated enterocytes and the loose junctions between the cells. Note, no obvious mass of endosymbiotic microflora can be observed. Scale bar = 10 μm.

microbes found on the epithelial surface of various mantle and digestive organs (foot, gills, labial palps, stomach, ciliary tufts, crystalline style and style sac, digestive gland, and fore-mid-hind intestinal tract) except in one animal (Fig. 1a-d). All epithelial layers of these tissues were covered in March and August with a heavy layer of mucus. Food particles, including bacteria, were often seen trapped in this mucus layer (Fig. 1e and f), but no attached bacteria or other microbes were associated with this mucus layer or below it on the surface of the epithelium itself. The one exception was a fungal mat growing on the mantle tissue, at the base of the excurrent siphon, collected from one *L. siliquoidea* in August (Fig. 2).

Even though no obvious attached microbes were seen, every unionid examined, from all sites, contained what appear to be attached round structures, possibly spores, in their intestinal tracts. These structures were always found below the mucus layer and between the enterocytes comprising the intestinal wall (Figs. 3 and 4). They were large, about 1μ in diameter, and were attached by a stalk to the unionid tissue (Fig. 4d and f). Though consistently seen, attempts to rear these spores (if that is what they were) in isolation, for further elucidation, failed.

Microbial Growth on Bacteriological Media

Microbial growth varied by locality, media type, and season but not by unionid species, replicate, organ source, or the presence or absence of oxygen. All (100% of the 336 samples) of the samples from the Huron River population collected in March and August

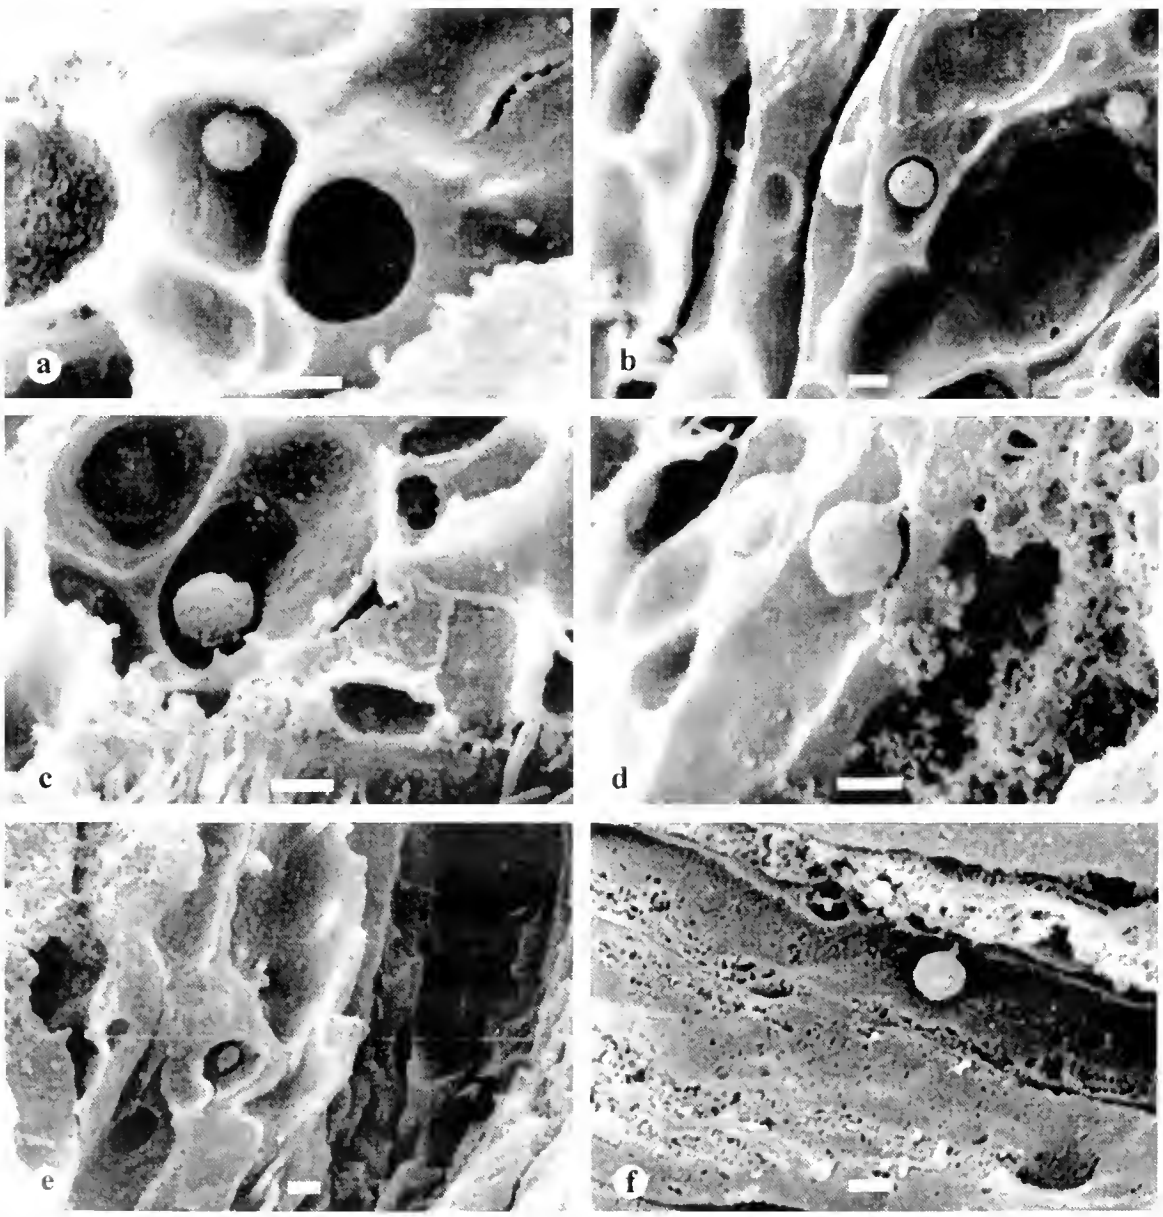

Figure 4. Scanning electron micrographs of the unidentified attached spore-like structures found in the intestinal tract of various species of freshwater unionids collected from several sites in southeast Michigan: (a) *Pyganodon grandis*, Huron River; (b) *Lampsilis siliquoidea*, Huron River; (c) *Lampsilis ventricosa*, Huron River; (d) *Ptychobranchus fasciolaris*, Huron River; (e) *Elliptio dilatata*, Vineyard Lake; and (f) Pyganodon *grandis*, Four Mile Lake. Scale bars = 1μm (a–e).

contained cellulose-, chitin-, and cellobiose-degrading bacteria, regardless of unionid species, organ from which the inoculant was obtained, or whether the sample was grown aerobically or anaerobically (Table 1). In all 336 samples, bacterial growth was noted within 12 h of inoculation based on gas production and clouding of the media. The bacterial communities developing in the cellulose and chitin media were similar in that all were motile, were fermenters, and facultative anaerobes (Fig. 5), but they differed in size. The rod-shaped bacteria growing in the chitin were longer (avg. 3.96 μm) than those in the cellulose media (avg. 2.26 μm). The bacterial community that grew in the cellobiose was dominated by non-motile cocci, which were also fermenters and facultative anaerobes. Rod-shaped bacteria were present, but even smaller in length (avg. 1.95 μm) than those found in the other types of media. However, in the December samples, none of the 112 samples inoculated in either cellulose or chitin showed any growth up to 120 hours. In contrast, the December cellobiose samples ($n=56$) did show a 100% response to this media within 12 h, regardless of unionid species, organ source, or whether the sample was grown aerobically or anaerobically.

The lake samples, *P. grandis* from Four Mile and *E. dilatata* from Vineyard, differed from Huron River unionids in that no microbial growth occurred in either cellulose or chitin media regardless of season, or organ source (total of 168 samples for both lakes) (Table 1). However, like the Huron River animals, these lake unionids consistently showed activity in 100% of the 84 cellobiose samples, regardless of season, lake, or organ source. As with the Huron River unionid cellobiose samples, the bacterial community growing on the cellobiose media was dominated by non-motile cocci that were fermenters and facultative anaerobes. In size and appearance they were identical to those observed in the Huron River unionid samples.

DISCUSSION

None of the unionids samples examined contained true endemic microflora. In order to be considered a true endosymbiont,

Response code: + indicates bacterial growth and media degradation occurred within 12 hours of culture; 0 indicates no bacterial growth seen from 12–96 hours after inoculation. Sample size differs and is discussed in the methods section of text.

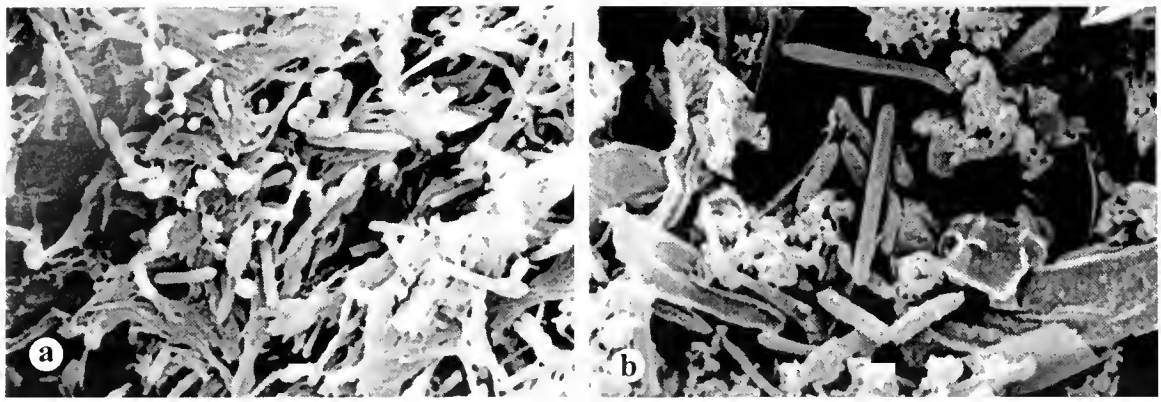

Figure 5. Scanning electron micrograph of the bacterial community cultured from the mantle cavity and gut content of freshwater Unionidae. (a) shows the bacterial community that developed in cellulose media, while (b) shows the community that developed in the chitin media. Scale bar = 1 μm.

microbial fauna must demonstrate certain characteristics which include: at least part of the endosymbiont community must be physically attached to the host's body tissues to ensure retention inside the animal; endosymbiont densities should be high ($>10^{10}$/g), and; the endosymbiont must be consistently found inside the host regardless of season or location (Yokoyama and Johnson 1993; Taylor et al. 1995). These criteria were not met. One problematic question remains regarding the unidentified spore-like structures attached or associated with every unionid intestinal tract we examined. Our inability to culture or isolate enough of these structures for further identification prevents us from labeling them as endosymbionts or to hypothesize their relationship with the unionid host. While in appearance and size these structures resemble the fruiting bodies, or zoospores, produced by fungus or a bacterium, a hyphal vegetative phase was only found once and in the mantle, not gut. The one exception, the fungal hyphae, attached to a specimen of *L. siliquoidea* (Fig. 2) and lacked spores or fruiting bodies. Even if these attached structures are spores, their limited numbers are not consistent with endosymbiont community criteria, and likely represent remnants of transient fauna. Fungi are a common component of the planktonic material drifting in the water of both Four Mile Lake and the Huron River (Nichols and Garling 2000). Occasional microbial spores are not uncommon in the intestinal tracts of some marine bivalves (Kueh and Chan 1985).

The presence of copious amounts of mucus in the mantle cavity and gut lumen of unionids (Fig. 1e) may mask or prevent the colonization of tissues by endosymbionts. Hyphal structures of fungi could easily be hidden in thick mucus layers. While surface-associated microsymbionts including fungi have been identified in many animals including fish (Mountfort and Rhodes 1991) and ruminants (Lowe et al. 1987; Sijtsma and Tan 1993) using the same techniques we used in this study, none of these vertebrates produce and utilize mucus in food handling and processing as do unionids. However, during December, when concurrent studies in the Huron River indicated unionids were not feeding (Nichols and Garling 2000), very little mucus was present inside the animals, and yet no attached microflora could be observed. A true endosymbiotic community would still have remnant, attached fauna, even when feeding was not occurring. Garland et al. (1982) have hypothesized that in oysters heavy mucus production prevents endosymbiont attachment on tissues. Such mucus hindrance might also limit the development of surface-attached endosymbiotic communities in unionids as well.

The variability of the results of attempted culture of microorganisms on cellulose or chitin media support our conclusion that unionids lack true endosymbiotic microbes capable of digesting these substrates. Microbial growth occurred on cellulose and chitin during periods that concurrent studies in the Huron River indicated the unionids were feeding (late February to late November, Nichols and Garling 2000). Similarly, microbial growth on these culture media did not occur during December when the unionids in this river were not feeding. If endosymbionts were present, we should have been able to culture them in December samples. The differences in microbial response to culture media, in combination with the fact that no microbes were found attached inside the unionids, indicate that cellulolytic and chitinolytic microbial communities represent transient fauna and not endosymbionts. The total lack of microbial growth in cellulose and chitin media by the Four Mile and Vineyard lake samples is surprising. Likely, this may correspond to significant differences in lake versus river microbial communities.

The ability to culture a microbial community on the cellobiose media from all unionids, regardless of species, season, or habitat, is certainly a trait associated with endemic microbial fauna. However, since no microbes were found attached to any unionid internal tissues, we have concluded that these starch-degrading microbes were transient fauna and not endosymbionts. While the spore-like structures found attached between the enterocytes of all unionid intestinal tracts could hypothetically be related to this cellobiose community, the lack of further identification of these structures prevents making this direct association.

Assuming primary cellulases and chitinases are not endogenously produced, the lack of cellulolytic or chitinolytic endosymbionts in unionids means that initial bond breakage must rely on transient microbial fauna. A reliance on such transient microbes could influence captive maintenance success if dry diets based on cellulose (corn/soybean) or chitin (nauplii) are fed to unionids. Efficient utilization of these feeds by these bivalves would require prior microbial predigestion in order to provide the necessary initial bond breakage to break these complex polysaccharides.

Unionids appear unique among aquatic invertebrates in that they consume detritus and yet lack microbial endosymbionts that would aid in digesting complex polysaccharides. While this may imply that detritus merely serves as a convenient substrate for preferred food items, i.e., attached epimicroorganisms, further work is needed to fully identify digestive enzymes produced by

unionids. Dependence of unionids on microbes appears complex and combines elements of selective predation, subsequent enhancement of non-prey species, and a reliance on transient fauna. Our observations do not support the endosymbiont model characteristic of well-known vertebrate/microbe associations. The role of transient microbial fauna, particularly the importance of different microbial species assemblages, may very well be key factors influencing unionid survival in relocation and aquaculture efforts.

METHODS FOR MASS REARING STAGES I–IV LARVAE OF THE AMERICAN LOBSTER, *HOMARUS AMERICANUS* H. MILNE EDWARDS, 1837, IN STATIC SYSTEMS

BRIAN F. BEAL[1]* AND SAMUEL R. CHAPMAN[2]

[1]*University of Maine at Machias, 9 O'Brien Avenue, Machias, Maine 04654;* [2]*Waldoboro Shad Hatchery, Waldoboro, Maine 04572*

ABSTRACT We conducted a series of five laboratory experiments (7–18 days in duration) to test the interactive effects of stocking density, aeration rates, and food types on survival of American lobster (*Homarus americanus*) larvae through their first three planktonic stages (I–III) to the postlarval stage (IV). Experimental units and culture protocols were designed to replicate a 1:100 scaled-down version of equipment used in association with a fishermen-sponsored, stock enhancement lobster hatchery located in Cutler, Maine. The first four trials revealed that extremely high rates of aeration (ca. 240 mL air sec^{-1}) were necessary to distribute larvae and food sufficiently to reduce cannibalistic encounters; however, the best survival from stage I–IV (at stocking densities of 7–26 L^{-1} fed *ad libitum* with enriched *Artemia*) was only 24%. The final experiment (stocking density = 20 L^{-1}) yielded a mean survival rate (± 95% CI) of 75.8 ± 10.2% (range = 62.7% to 90.7%; n = 6). One important difference between the last and first four experiments was how stage I larvae were managed prior to their culture. In the first four trials, unfed larvae were collected from a relatively small (46 cm × 30 cm × 20 cm), screened capture basket located near the discharge pipe of a broodstock holding tank at the hatchery where they may have resided for > 12 hr. Larvae used in the final laboratory experiment were collected directly from the broodstock tank within 30 min after being liberated from the mother's swimmerets. Larvae, at relatively high densities within the screened box, likely had many more cannibalistic encounters prior to their culture than those collected directly from the broodstock tank and, therefore, suffered high rates of mortality during the first four laboratory trials. Mass rearing methods for larval American lobsters developed in conjunction with these laboratory experiments were used successfully by staff at the Cutler Marine Hatchery from 1988 to 1992. During this period, survival from stages I–IV averaged 44%, and approximately 875,000 stage IV animals were released to the wild. These culture methods have withstood the test of time as a private lobster hatchery in Maine adopted our protocols in 1993, and they continue to be in use. Further, the general techniques described here have been used since 1994 to culture European lobsters (*Homarus gammarus*) at a commercial lobster hatchery in the southeast of Ireland.

KEY WORDS: lobster, *Homarus americanus*, culture, static systems, stock enhancement, *Artemia*, microalgae, stage IV larvae

INTRODUCTION

Mass production of juvenile lobsters (*Homarus americanus* H. Milne Edwards) for stock enhancement programs began as early as 1872 in the United States (Rathbun 1886). Lobster "parks," natural tidal impoundments, were used in Maine and Massachusetts as spawner sanctuaries where egg-bearing females were held until releasing their stage I larvae. The earliest lobster hatchery was established in 1883 at Woods Hole, Massachusetts. Here, eggs were detached from females, placed into hatching jars, and stage I lobsters released to the wild (Nicosia and Lavalli 1999). In time, enhancement of lobster stocks using early planktonic individuals was abandoned in favor of methods to rear larvae for release at their earliest benthic stage (reviewed in Nicosia & Lavalli 1999).

Perhaps the most successful long-term stock enhancement effort in the United States with respect to juvenile production occurred at the Massachusetts State Lobster Hatchery and Research Station on Martha's Vineyard from 1951 to 1997. Culture protocols and equipment were developed that became the standard for production of massive numbers of stage IV individuals (Hughes 1972, Hughes et al. 1974). In particular, a 40-L round-bottom rearing vessel, or kreisel, was invented that, with sufficient flow rates (ca. 10 L min^{-1}), provided enough turbulence to distribute homogeneously both larvae and food, and minimized cannibalistic encounters (Hughes et al. 1974). Stocking these kreisels with 2,000 stage I larvae of *H. americanus* and supplying them with live brine shrimp (*Artemia salina* L.) during the ten to fourteen days in culture reportedly resulted in survival rates to stage IV between 75%–85% (Hughes et al. 1974, Serfling et al. 1974a, Schuur et al. 1976, Van Olst et al. 1980, Aiken & Waddy 1989, Waddy and Aiken 1998). Improvements on the basic design enabled the culture system to operate efficiently either using recirculating or flow-through seawater (Serfling et al. 1974a, Schuur et al. 1976, Van Olst et al. 1977). During the past three decades, the "Hughes pot," or planktokreisel, has been used widely by scientists in the United States and Canada to produce large numbers of juvenile lobsters for enhancement of wild stocks, commercial operations, and laboratory and field experiments. In addition, similar larval culture systems have been used in Europe with *H. gammarus* L. (Beard & Wickins 1992, Burton 1992, Browne 1999).

In Maine, during the mid-1980's, lobster fishers decided they wanted to fund up to five lobster hatcheries along the coast to produce stage IV individuals for stock enhancement purposes (Plante 1986). At the same time, one of us (S. Chapman) was working on a simple system to rear lobster larvae from stages I–IV in 400-L conical tanks similar to those used to culture bivalve larvae (Castagna 1983). The process involved culturing phytoplankton to enrich brine shrimp that were then added (after a period of growth) to static culture tanks containing lobster larvae. The work was carried out primarily because Chapman was unable to repeat the success of others using the smaller 40-L kreisels (Hughes et al. 1974) and he was interested in developing culture protocols that could be transferred easily to groups of fishers.

In 1986, the first fishermen-sponsored stock enhancement program for lobsters in Maine was initiated in the eastern coastal community of Cutler, and the Cutler Marine Hatchery (CMH) was created (Nicosia & Lavalli, 1999). From 1986 to 1992, this program was the only enhancement effort funded by lobster license fees through Maine's Department of Marine Resources. Although we both served as technical advisors to CMH during this time, the

*Corresponding author: E-mail: bbeal@acad.umm.maine.edu

hatchery was managed by a fisherman and elderly housewife who, before that time, had no technical training in any aspect of the biological sciences.

During the first months of production at CMH in 1986, survival rates of stage I–IV lobster were very poor (< 10%). Here, we describe a series of five sequential laboratory experiments conducted between July and October 1986 that were designed to improve on this survival rate.

MATERIALS AND METHODS

A series of five larval lobster culture experiments (A–E) were conducted at ambient room temperatures at the University of Maine at Machias (UMM) between 15 July and 17 October 1986. Experiments were designed to assist staff at the CMH with culture protocols to maximize lobster larvae survival from stages I to IV. At UMM, it was not possible to replicate the culture vessels employed at Cutler's Hatchery (ca. 400-L conical-shaped fiberglass tanks filled to 375 L and aerated from the apex of the cone). Instead, we used 4.73-L plastic, flat-bottomed, round buckets (25.4 cm diameter at the top, tapering to 20.3 cm diameter at the base). A 3.2 mm hole was drilled in the middle of the bottom of each bucket (experimental unit) and a ceramic air stone fitted into each hole. A piece of tubing connected each ceramic stone to a manifold that received a supply of air from a pump (1-hp Conde, Westmoor Ltd., Sherill, NY). All experiments were conducted in 3.78 L (1 gallon) of seawater, which represented approximately 1/100th of the water volume used at Cutler. Buckets were not covered; therefore, photoperiod varied from one experiment to another. An attempt was made to determine if experimental results could be repeated at the Cutler Marine Hatchery (see Results—Experiment B).

Stage I lobster larvae used in Experiments A–D (Table 1) were collected at 0700 hr from a screened wooden box (46 cm × 30 cm × 20 cm) located near the discharge pipe of a broodstock holding tank at CMH, where they may have resided for > 12 hr. Larvae were transferred immediately to moist paper toweling nested within a stainless steel sieve (64 μ), placed inside a styrofoam cooler, and transported to UMM (a process that took between 30 to 45 min). Larvae used in Experiment E were taken directly from the broodstock tank with a small fish net only moments after they had been liberated from the mother's swimmerets (*sensu* Talbot and Helluy, 1995). Filtered (1 μ) seawater used in all experiments was collected at CMH.

At UMM, larvae were immediately transferred to a 40-L aquarium from which individuals were removed, counted, and added to experimental units containing a source of food (see below). We assumed that animals transferred to experimental units were unaffected by our handling, although we did not conduct a specific handling experiment. We used only larvae that were swimming prior to initiating each experiment. Every 48 hours until the end of an experiment, larvae in this static culture system were poured through a nylon fish net (1 mm aperture) that retained

larvae and any uneaten food. Larvae were returned immediately to a clean (rinsed with 60° C freshwater) bucket containing 3.78 L of seawater (room temperature) and food.

Live brine shrimp (*Artemia salina*), used as a source of food in Experiments A, B, D, and E, were reared in 40-L glass aquaria at UMM. *Artemia* were fed algae (Tahitian *Isochrysis galbana* Parke [clone T, iso] and *Chaetoceros gracilis* Ehrenberg) *ad libitum* that had been cultured at CMH. Brine shrimp were cultured for four days (total length ca. 2–3 mm) at a temperature of 30 C under constant fluorescent lighting before transferring to experimental units (ca. 40 brine shrimp per mL). In all experiments, there was always an excess number of live brine shrimp in experimental units after 48 hours. This number was estimated by counting a 1 mL sample from each unit using a Sedgewick-Rafter cell. These excess brine shrimp were returned to the experimental unit from which they had come and new, four day-old brine shrimp were added to bring the density to 40 mL^{-1}.

In Experiments A and B (Table 1), aeration rate was one of two factors tested. Altogether, three aeration rates were examined (Low = 20 mL air sec^{-1}, Moderate = 80 mL air sec^{-1}, High = 240 mL air sec^{-1} as measured crudely using a water displacement technique). Qualitatively, the low flow rate resulted in a few small air bubbles per second. Water movement was minimal and restricted to a small column the width of the air stone (ca. 20 mm) in the center of each bucket. At low aeration, both larvae and brine shrimp were visible; however, lobster larvae appeared to congregate on or near the bottom of the buckets. With moderate aeration rates, water motion also was restricted to the center of the buckets, although the diameter of the circulation zone was larger (ca. 80 mm). At this flow rate, larvae were moved in a gentle upward motion and then immediately downward in a vertical circulating current. High rates of aeration resulted in vigorous vertical and lateral movement of larvae throughout the water column. Larval motion was too rapid to observe individuals. At these aeration rates, the water surface within each bucket was moving so rapidly that it appeared to be boiling.

Experiments A–D were completely factorial with two fixed factors per trial. Experiments were sequential in that results from a particular trial were used to design the ensuing trial. In Experiments C and D, food type was varied. For Experiment C, 6–8 mm pieces of fresh soft-shell clam, *Mya arenaria* L., mantles and similar sized frozen adult brine shrimp were used to feed lobster larvae. In Experiment D, 6–8 mm pieces of fresh clam and frozen and thawed muscle tissue from mackerel (*Scomber scombrus* L.) were added to experimental units containing live, algal-enriched brine shrimp. In Experiment E, octagonal strips (33 cm × 33 cm) composed of extruded, black plastic netting (6.4 mm aperture) were positioned at a 45° angle within six experimental units. Netting extended from the bottom of the experimental unit to a few cm above the surface of the seawater. The purpose of the netting was to increase spatial heterogeneity within the experimental units and provide a surface or substrate for larvae to encounter and, potentially, reduce conspecific cannibalistic encounters. Another six units served as controls (no netting).

For Experiments A–D, a two-factor, model I analysis of variance (ANOVA) was performed on the angular-transformed percent survival data (Sokal and Rohlf 1995). Orthogonal, *a priori* contrasts were performed for each source of variation with more than a single degree-of-freedom (see Results). A single-factor, model I ANOVA was performed on the angular-transformed percent survival data from Experiment E. In all cases, the transformation served to either normalize the data (Shapiro-Wilks test [SAS 1998]) and/or homogenize variances (Cochran's Test [Winer et al. 1991]).

RESULTS

Experiment A

The experiment was terminated on day seven because excessive heat inside the laboratory on 21 July (32° C), in addition to high cannibalism rates during the first six days, resulted in the deaths of 98% of the larvae. Only 41 stage III individuals of the initial 500 larvae stocked in the experimental units (Table 1) were alive on 21 July. There was no cumulative effect on survival to this stage due to density ($P = 0.094$); however, nearly 9× as many larvae survived the seven-day trial in experimental units receiving moderate (37 animals) versus low (4 animals) rates of aeration ($P = 0.021$).

Experiment B

Seawater temperature varied throughout the experiment from 19° to 24° C, which is within the range of natural conditions experienced by *H. americanus* larvae (Van Olst et al. 1980). Salinity was constant at 31 ppt. Eight days after the experiment was initiated, a mean of at least 88% mortality had occurred in all treatments (Table 2). By this date, all surviving larvae ($n = 216$) had reached stage III in their development. On 11 August, fourteen days after the experiment was initiated, only 124 of 900 (13.8%) larvae remained across all six treatments of which 119 (96%) had metamorphosed to stage IV. ANOVA revealed that all main and interaction sources of variation were significant ($P < 0.05$; Table 3). The effect of aeration rate on mean survival depended on stocking density. *A priori* contrasts indicated that 7.7% of the larvae reared at 100 $unit^{-1}$ (ca. 26 L^{-1}) survived from stage I to IV independent of aeration rate. This was nearly twice the average

TABLE 2.

Percent survival (±95% CI) of larval lobsters in Experiment B (28 July to 11 August 1986).

Density	Aeration	Day 6	Day 8	Day 10	Day 12	Day 14
100	Moderate	21.5 (12.35)	9.7 (1.47)	7.3 (1.43)	6.0 (4.31)	5.7 (2.87)

A priori contrasts appear with density and interaction sources of variation. See Table 2 for aeration rates. $n = 3$.

survival rate (3.8%) of larvae at the two higher densities ($P = 0.0003$). High aeration rates significantly improved survival rates of larvae stocked at 150 unit^{-1} (40 L^{-1}) compared with moderate aeration rates, but this same improvement did not occur for larvae initially stocked at 200 unit^{-1} (53 L^{-1}).

Because this experiment had shown that high aeration rates (ca. 240 mL air sec^{-1}) and a density of 100 L^{-1} may result in 5–10% survival, a two-week test of these culture variables was initiated in three 400-L conical tanks at CMH from 11 to 25 August. Culture vessels at Cutler were treated similarly to those in the laboratory. We used algal-enriched, live brine shrimp (40 mL^{-1}) as a source of food and added approximately 10,000 stage I larvae to each vessel, which was aerated vigorously. A regression equation was developed using mass (g) and larval number to estimate number of stage I larvae stocked per conical tank (Fig. 1a) and number of stage IV larvae (Fig. 1b). These equations enabled us to estimate percent survival on a per-tank basis over the two-week culture period at CMH.

Culture conditions at Cutler were very similar to those at UMM. Seawater temperature varied between 20° and 24°C and salinity was 31 ppt during the two-week interval. Survival of stage I to IV larvae in the three conical tanks was: 7.5%, 10.2%, and 4.9%.

Experiment C

Previous experiments had demonstrated that mortality between stages I and III was severe (usually > 90%) in both the large conical tanks at CMH and the experimental units at UMM. Because we observed many cannibalistic encounters during the first week, one possible explanation for this might be that larvae preferred a larger food particle than the 2–3 mm brine shrimp.

Seawater temperature varied between 21.5° and 24°C and salinity fluctuated between 31 and 34 ppt. On 15 August, four days after the experiment was initiated, survivorship summed across all treatments was 24.1% (Table 4). When the experiment was terminated on 25 August, mean survivorship over all treatments was 1.5%. ANOVA (Table 5) demonstrated both a density and food type effect. Larvae survived best (2.4%) at the lowest density (50 unit^{-1}) and frozen brine shrimp provided a significantly higher survival rate (1.9%) than chopped soft-shell clam (1%) ($P = 0.0307$, Table 5).

Experiment D

Because the extremely poor survival rates observed in the previous experiment suggested that larger food particles, alone, should be rejected as a source of food for culturing lobster larvae, we examined the interactive effects of diet (large food particles [6–8 mm pieces of clam and mackerel] together with live brine shrimp) and stocking density (25, 50, 100 larvae unit^{-1}).

Seawater temperature varied between 17° and 23°C and salinity between 31 and 35 ppt during the 18-day trial. On 16 September, an experimental unit from the low-density fish treatment was found without water. All larvae inside were dead and this replicate was removed from the experiment. During the final two days of the experiment (20 to 22 September), all four larvae found in one experimental unit from the high-density fish treatment appeared to have become infected with the ciliate *Vorticella* spp. No other larvae appeared to have the ciliate.

Unlike previous experiments, overall mortality did not exceed 80% until the 16th day of the experiment (20 September, Table 6). The experiment was terminated on day eighteen when 96% of the individuals had metamorphosed to stage IV (Table 7). Because it is not possible to separate efficiently stage III from stage IV individuals, Table 7 can be used as a guide in developing strategies for releasing early benthic phase *H. americanus* from hatcheries (such as Cutler) that do not have space to rear stage IV + animals to larger sizes either individually or communally. For example, on Day 14, 35% of the animals were at stage III while 65% were at stage IV ($0.65 \times 180 = 117$ stage IV individuals). Two days later, 94% of the remaining larvae were stage IV ($.94 \times 143 = 134$). The additional 48 hours yielded 15% more stage IV individuals even though the percent of individuals reaching the fourth stage increased over this same time interval by nearly 30% (65% to 94%). This suggests that both overall percent survival and percent of individuals that have attained the first benthic stage should influence decisions when to release larvae to the wild.

ANOVA (Table 8) was unable to detect a difference in mean survival between the two food types (clam + live brine shrimp = 19% vs. mackerel + live brine shrimp = 13%, $P = 0.084$). There was no overall effect due to density; however, the *a priori* contrast of low (22%) vs. the mean of the two higher densities (13%) was significant ($P = 0.048$).

Although mean survival at the lowest density was better than in previous experiments (Table 6), these rates were much lower than published accounts of lobster larval survival to stage IV, either by other public hatcheries (e.g., the Massachusetts State Lobster Hatchery at Oak Bluffs, Martha's Vineyard, MA, Hughes et al., 1974) or research laboratories (Serfling et al. 1974; Schuur et al. 1976; Aiken et al. 1981; Eagles et al. 1984).

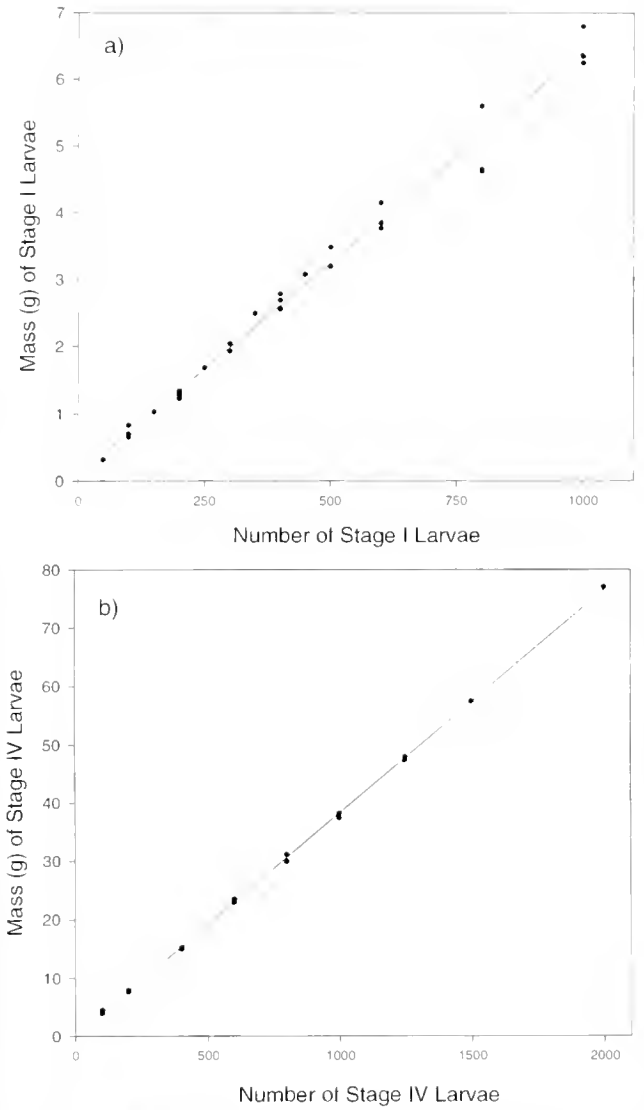

Figure 1. Mass(g)-to-number relationships for stage I (a) and IV (b) larvae of *Homarus americanus*. (Stage I: Y = 0.0824 + 0.00633 X, n = 30, r^2 = 0.988, 157.9 larvae g^{-1}; Stage IV: Y = 0.0896 + 0.03821 X, n = 16, r^2 = 0.999, 11.2 larvae g^{-1}). Larvae of both stages were caught using a nylon mesh (1 mm aperture) and transferred to a sieve (125 μ). A piece of paper toweling was used to absorb moisture from the bottom of the screening for 30 seconds before measuring mass using a Sartorius electronic balance to the nearest 0.01 g.

Experiment E

Seawater temperature varied between 17° and 22°C and salinity between 30 and 33 ppt. For no apparent reason, all larvae within one of the buckets containing a strip of the plastic netting died within the first 36 hours. On Day 15, 83% of all surviving individuals had reached stage IV. When the experiment was terminated 48 hours later, 98% had metamorphosed to stage IV. Dramatic differences in survivorship occurred between this test and all previous experiments (Fig. 2). By the end of the experiment, 18.1 ± 13.9% (95% CI) (range = 6.7% to 34.7%) of the animals in the experimental units containing plastic strips had survived to stage IV whereas 75.8 ± 10.2% (range = 62.7% to 90.7%) of the larvae attained stage IV successfully in the control units. These survival rates were highly significantly different ($P < 0.0001$)

Transfer of Techniques from the Laboratory to the Cutler Marine Hatchery

In 1986, an estimated total of 20,000 stage IV lobsters were released from CMH. The best survival rates observed during that season, which lasted from mid-June to mid-September was 12.5% (25 August to 9 September; Beal, pers. obs.). In 1987, using techniques learned from Experiment E (above), approximately 93,000 stage IV animals were released from CMH during a similar time interval. Survival rates were as high as 60%, but averaged 42% for the year (Beal, unpubl. data). From 1988 to 1992 (the last year CMH operated), an average of 175,000 stage IV lobsters per year were released by staff at CMH into coastal waters near Cutler, Maine (Beal et al. 1998). During that time, survival in the 400-L conical tanks varied between 25% and 65% with an average of 44%.

DISCUSSION

Experimental results and observations involving the initial handling of stage I lobster larvae described here led to the adoption of culture techniques that enabled staff at Cutler's Marine Hatchery to become successful in rearing *Homarus americanus* larvae through their planktonic stages (I–III) to first benthic stage (IV) for stock enhancement purposes. That program operated from 1986 through 1992 when public funding for lobster hatcheries in Maine ceased. The culture techniques described below have been in use since 1993 by staff at a private facility in Maine (the Southwest Harbor Oceanarium, SHO) who are engaged in stock enhancement efforts in the waters near Bar Harbor, Maine (T. Montague, hatchery manager, SHO, pers. com., 7 July 2000). In addition, similar culture techniques have been adopted for *Homarus gammarus* production of stage IV animals for stock enhancement efforts in Ireland (Browne & Mercer 1988).

In Maine, wild broodstock were obtained from fishers on an as-needed basis. Maine's Department of Marine Resources issued special permits annually to those who were active in the CMH stock enhancement program. (Aiken and Waddy [1985] reported that in Canada, it was difficult to obtain egg-bearing females from fishers. This led them to develop methods to domesticate broodstock for year-round seedstock production). In eastern Maine, broodstock with eggs ready to hatch (i.e., those that display a light bluish hue), were commonly available beginning the second week of June through mid-September from 1986 to 1992 (Beal, pers. obs.). Beginning in 1987 and continuing through the 1992 season, egg-bearing females entering CMH were immediately bathed in a 1% solution of Betadyne (povidone iodide) in filtered (1 μ) seawater to remove fauna and ectoparisites such as copepods, nematodes, or *Vorticella* spp., as well as reduce the probability of bacterial infections. The bath consisted of immersing the entire animal, except its mouthparts and gills, for 8–10 min. Egg-bearing females were then moved to a static, communal tank (1,320 liters) that was completely covered to provide constant darkness. No more than five female lobsters were held in this tank at any time. Ambient, filtered (1 μ) seawater in the tank was changed every two days and the tank thoroughly cleaned on a weekly basis. Hatching occurred generally throughout the day, but the hatching period for a particular female lasted no more than five days (see Hughes and Matthiessen 1962). Stage I swimming larvae were taken from the broodstock tank within 30 min of being expelled from the clutch using a small nylon aquarium fish net. Sometimes, large batches of stage I larvae were available early in the morning

Density = number per 3.78 L. Aeration (High = 240 mL air sec^{-1}). Diet (6–8 mm pieces): soft-shell clam (*M. arenaria*) or frozen brine shrimp. Day refers to days after hatching. $n = 3$.

(i.e., after CMH staff came to work ca. 0700); however, these larvae were not added to culture tanks. Instead, they were liberated because results from Experiments A–E suggested that a dense assemblage of unfed stage I larvae would not do well under culture conditions.

After collecting recently hatched larvae, each netted batch was weighed to provide an estimate of numbers placed into a 400-L culture tank (Fig. 1a). Over a two-day period, between 7,500 and 10,000 stage I larvae were added to a vigorously aerated (from the apex of the cone) conical tank filled to ca. 375 L (ca. 20–27 larvae L^{-1}). Tanks contained 275 L of seawater (18°–20°C) plus 100 L of a 1:1 mixture of the flagellate Tahitian *Isochrysis galbana* and the diatom *Chaetoceros gracilis* or *C. mulleri* Ehrenberg at a cell density of $2–4 \times 10^6$ cells mL^{-1}. In addition, lobster larvae received a supply of live, four day-old *Artemia* (initially 40–50 mL^{-1}) that were cultured and enriched at CMH.

Approximately 80 mL of dry brine shrimp eggs (Aquarium Products®, Glen Burnie, MD) were first decapsulated (Bruggerman et al. 1980) and then added to a 400-L conical tank containing only 100 L of filtered (1 μ) seawater (25°–29°C). After brine shrimp had hatched, the tank was filled with cultured algae (as above). After four days, the tank was drained and brine shrimp (ca. 3 mm) retained on a small sieve, the contents of which were added to one 400 L conical tank with larval lobsters.

Lobster larvae remained in the static culture tanks for two days before being transferred to an adjacent, clean tank containing vigorously aerated seawater, microalgae, and brine shrimp. The transfer process lasted no more than two minutes. We devised a dip net that was approximately 40 cm long × 30 cm wide × 20 cm deep made from nylon window screening. To transfer larvae, we would dip once from the larval tank and immediately empty the contents of the net into the clean tank. After six to seven dips, 95% of the larvae had been transferred. Next, we turned off the air and drained the seawater from the larval tank, quickly capturing the remaining larvae on a sieve (500 μ). This method also retained uneaten, live brine shrimp that also were added to the clean tank along with the lobster larvae. This transfer process continued for approximately two weeks, or until 85–90% of the surviving larvae had reached stage IV, when they were released to the wild. It never was necessary to add any antibiotics or other medication to a culture tank. From 1988–1992, survival rates from stage I to IV at CMH averaged 44%. These early benthic phase animals were released at depths of 10–20 m on or near cobble bottom in along a 170 km stretch of coast from Cutler (44°14′N, 67°27′W) to Tenant's Harbor (43°33′N, 69°03′W) Maine.

The larval culture techniques employed at CMH were different from methodologies that had been used to that date (Hughes et al. 1974; Serfling et al. 1974a; Schuur et al. 1976; Van Olst et al. 1980) primarily because of work conducted at the University of Maine's Darling Marine Center (DMC, Walpole, ME) from 1983-1985 by one of us (S. Chapman). Prior to the mid-1980's, most culture work on planktonic American lobsters was conducted in 40 L round-bottom, fiberglass tanks known as kreisels, planktokreisels, or "Hughes pots," after work published by John Hughes, former director of the Massachusetts State Lobster Hatchery (MSLH; Oak Bluffs, Martha's Vineyard, MA; Hughes et al. 1974) and his colleagues in California (Serfling 1974b; Ford et al. 1975; Van Olst et al. 1977). Highest estimated survival rates to stage IV per kreisel (35–85%) occurred when stage I larvae were stocked at densities between 500 and 3,000 (12.5–75 L^{-1}) and fed either live or frozen *Artemia* throughout the culture period (Hughes et al. 1974). Van Olst et al. (1980) reported that, "When food and larvae are uniformly distributed and proper densities of both are maintained, larval survival to stage IV will average 60–75%." Schuur et

Density = number per 3.785 L. Aeration (High = 240 mL air sec^{-1}). Diet (6–8 mm pieces): soft-shell clam (*M. arenaria*) or mackeral (*Scomber scombrus*) in combination with four day-old, enriched live brine shrimp (*Artemia salina*). Day refers to days after hatching. $n = 3$.

al. (1976) reported that a maximum survival rate of 70% can be attained when 1500 larvae from a single day's hatch are added to a "Hughes pot" and are fed live brine shrimp over a two-week period at temperatures of 20.0 ± 0.5°C. Although a number of studies used these culture techniques (Hughes et al. 1974; Serfling et al. 1974a, Schuur et al. 1976), none indicated how final numbers of stage IV animals were counted, none provided estimates of mean survival or variability, and none described how larvae were handled prior to stocking each kreisel.

One of us (B. Beal) visited MSLH in November 1991. At that time, it was reported by staff that survival rates of larval lobsters from stages I to IV at MSLH typically were in the range of 15–20% and rates had been at those levels for many years (M. Syslo, director, MSLH, pers. com., 7 Nov. 1991). At that time, 40-L planktokreisels were being used as culture vessels and frozen brine shrimp used as a food source. Stocking densities of stage I larvae were estimated to be 2,000 per culture vessel.

Several published accounts from Canada suggest good success in rearing American lobsters from stage I–IV in planktokreisels (Aiken et al. 1981; Aiken and Waddy 1989; Aiken and Waddy 1995; Eagles et al. 1984; Waddy 1988; Waddy and Aiken 1998). Aiken and Waddy (1995) indicated that a diet of frozen brine shrimp will produce survival rates of 35–65%; however, Eagles et al. 1984 noted that these highly variable survival estimates were related to the quality of frozen brine shrimp. Waddy and Aiken (1998) reported that maximum stocking density of stage I larvae into 40 L kreisels at the St. Andrews Biological Station (St. Andrews, New Brunswick) was "50–75 larvae per liter" (2,000–3,000 per kreisel). Best survival rates occurred at 20°C when live adult brine shrimp were maintained at a ratio of four/lobster larvae. Although Waddy and Aiken (1998) gave no specific survival rates, they referred to Schuur et al. (1976) for a range of estimates from stage I to IV (60–75%).

According to Serfling et al. (1974a), a system to mass culture *Homarus americanus* larvae must: (1) provide water circulation enough so as to suspend both food and lobster larvae without eddies or still-water pockets; (2) use a filtration system that maintains a well-oxygenated and high water quality independent of the seawater source; (3) be operable on a fully-closed, recirculating basis for several weeks; (4) function without continuous surveillance and operate independent of outside electrical power and water supplies; (5) have temperature control; (6) have provisions for effective control of diseases; and (7) be relatively maintenance free, inexpensive, and easy to build. The system used at CMH and elsewhere (see below) was developed primarily to enable non-scientists working in non-academic or non-research settings to culture *H. americanus* larvae to stage IV. Although the culture parameters outlined by Serfling et al. (1974a) have been successful in some settings, they assume a degree of technical sophistication (especially the filtration and recirculating systems) that usually does not exist in the situations we have been working for the past two decades (i.e., with fishers and their family members).

Our culture approach uses large volumes of air to suspend and disperse both lobster larvae and food (live, enriched brine shrimp) inside large, 400-L cone-shaped tanks. These methods depend on clean seawater, and function well for two-day intervals before the entire system must be cleaned and larvae transferred to another tank. Because CMH was relatively small ($60 m^2$), we found the most efficient method of keeping seawater temperature reasonably constant was to use an air conditioner. One of the most important

Refer to Table 6 for specific information about food type. $n = 3$.

pieces of information we discovered during our experimental trials that subsequently influenced our culture practices was in the timing of collection of the stage I larvae from the broodstock tank. We have been unable to find many specific references in the literature concerning this aspect of culturing lobsters. Aiken and Waddy (1995) state, "Hatching larvae are screened from the outflow of the maternal female's tank each evening and stocked in specially designed larval tanks (planktokreisels) that disperse water in an upward rotation that keeps the larvae in uniform suspension, reducing injury and cannibalism." Sastry (1975) and Chang and Conklin (1993) each describe a broodstock holding/larval collection system similar to those used at CMH in 1986. That is, filtered seawater flows unidirectionally into individual compartments holding egg-bearing females, which carries stage I lobsters into plexiglass catch baskets (no size given) with 1 mm mesh screening. "Each morning the removable catch baskets are examined for larvae, and, if present, the larvae are rinsed into a larval-rearing system" (Chang and Conklin 1993). Baskets facilitate the ease with which stage I larvae are collected and transferred to kreisels; however, we abandoned their use at CMH after 1986. We found both experimentally and in routine culture situations that, because of their cannibalistic tendencies, stage I larvae, if confined to small areas at high densities without *Artemia* or other food, either die immediately or become stressed or injured, resulting in high rates of mortality (i.e., > 50%) within the first week of culture (e.g., Experiments B–D). If capture or collection baskets were emptied often enough (i.e., before a critical density occurred within each), they would be useful. Instead, we opted to place 3–5 broodstock at a time in a small (1320 L), covered, static, lightly–aerated tank and collected larvae periodically (every 30–60 min) through the day using small, aquarium, fish nets. Stage I larvae hatched during the evening were not added to culture tanks at CMH; instead, they were liberated in a cove adjacent to the hatchery.

The culture methods outlined here are not specific to the American lobster. In 1992, a lobster (*Homarus gammarus*) stock enhancement effort was initiated in Ireland at the National University of Ireland, Galway Shellfish Research Laboratory (SRL) in Carna (53° 18′ N, 9° 49′ W). The system was based on using 40-L kreisels (Hughes et al. 1974) that were connected to a heated seawater reservoir system (18°C). Stage I larvae (density = 25–37 L^{-1}) were suspended by a continuous flow of recirculated seawater at 9 L min^{-1} and fed a combination of chopped mysid shrimp (*Neomysis* spp.), mussel (*Mytilus edulis* L.), and occasionally supplemented with live *Artemia*. After 17 days, survival rates were 9.8% (Browne 1999). In March 1993, the culture system was converted to one more closely resembling the one at CMH (Browne 1999; Beal, pers. obs.). Similar mass-to-number relationships were discovered for stage I *H. gammarus* larvae (Browne 1999) so that careful stocking estimates could be obtained. After 11–14 days in the hatchery, Browne and Mercer (1998) observed an average larval survival rate to stage IV of 47%.

The culture techniques used at SRL were transferred to a fishermen's cooperative lobster hatchery in southeast Ireland during the mid-1990's. In August 2000, one of us (B. Beal) visited this hatchery (Carne, County Wexford, Ireland) where lobsters have been produced for stock enhancement since 1994. The culture methods used are similar to those described by Browne and Mercer (1998) and Browne (1999). Stage I larvae are collected soon after release by the female and are placed into vigorously aerated seawater (18°–21°C) within 80 L conical tanks (hoppers) at densities

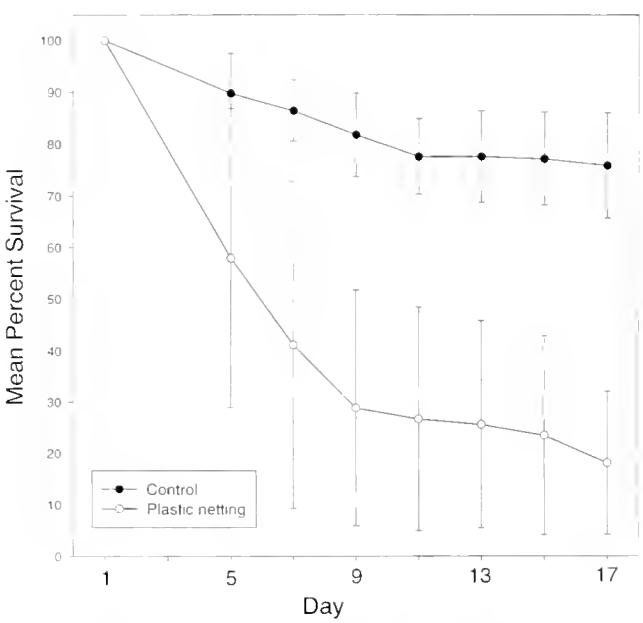

Figure 2. Experiment E. Mean percent survival ± 95% CI of *Homarus americanus* larvae through time for control (●) ($n = 6$) experimental units and those containing a piece of extruded, plastic netting (○) (6.4 mm aperture, $n = 5$). Larvae were stocked at 75 $unit^{-1}$ (ca. 20 L^{-1}), fed four day-old live brine shrimp and received vigorous aeration (i.e., 240 mL air sec^{-1}) during the entire experimental interval. Experiment was terminated on day 17 after 98% of larvae had metamorphosed to stage IV.

of 1500–2000/tank (19–25 L^{-1}). Tanks contained two species of cultured phytoplankton (Tahitian *Isochrysis galbana* and *Chaetoceros gracilis*) and live, algal-enriched brine shrimp. Larvae are transferred every second day to freshly prepared hoppers. Survival rates of lobster larvae from stage I to IV average 45% according to hatchery staff (N. Perrella, hatchery manager, pers. com., 24 August 2000).

Culture of *H. gammarus* for stock enhancement also took place in the United Kingdom in Wales and Scotland for nearly two decades beginning in 1973 (Beard et al. 1985, Lee and Wickins 1992, Wickins 1998). Larvae, stocked at 25 L^{-1} and fed twice daily with mysid shrimp (*Neomysis* spp.) and supplemented three times per week with newly hatched *Artemia* nauplii (Beard and Wickins 1992), were cultured in 100 L modified Hughes pots (planktokreisels) containing 80 L of seawater (16°–19 C). Flow rates of 7.5 to 12 L min^{-1} kept larvae and food suspended for the 11–17 days it took to reach stage IV. Survival rates (10–15%) of stage I to IV at the Ministry of Agriculture, Fisheries and Food's (MAFF) Fisheries Laboratory at Conway, North Wales were much lower than those reported from the two culture facilities in the Republic of Ireland (Beard et al. 1985, Beard and Wickins 1992). Similar survival rates were obtained at MAFF's Seafish Marine Farming Unit in Ardtoe, Scotland by Burton (1992).

The culture techniques described here are relatively simple, straightforward, and have withstood the test of time in a variety of hatch-and-release settings both in Maine (*Homarus americanus*) and Ireland (*H. gammarus*). Experiments A–D and the first year of production at CMH (1986) demonstrated that keeping lobster larvae and food well suspended within culture containers is important, but, without careful management of stage I larvae (i.e., collecting for culture within 30–60 min of release by the female), typical survival rates from stage I to IV will be less than 15%. Our techniques that produced a range of survival rates from 60% to 90% in the laboratory are not intended to replace those described elsewhere (Hughes et al. 1974, Serfling et al. 1974a, Van Olst et al. 1977, Aiken and Waddy 1989, Lee and Wickins 1992). These, too, have been used successfully in a number of disparate locations and production scenarios. Rather, we believe the culture methods described here provide another option for fishers, mariculturists, or research scientists to produce large numbers of stage IV clawed lobsters for stock enhancement, commercial enterprise, or experimental purposes.

ACKNOWLEDGMENTS

We wish to thank the community and fishers of Cutler, Maine and, especially, the Cutler Marine Hatchery Committee for their encouragement and assistance with this project. The manuscript was improved by R. Browne, J. Hinson, and A. Lewis. Funding for culture work at the Darling Marine Center was provided by the University of Maine and the Maine/New Hampshire Sea Grant College Program. Funding for Experiments A–E was provided by the University of Maine at Machias. We thank the Population & Community Ecology class at UMM for assistance on Experiments D and E. The manuscript was prepared while B. Beal was a visiting Fulbright Professor at the National University of Ireland, Galway and he thanks the Zoology Department and staff at the Martin Ryan Institute for providing office space and supplies during his stay.

ABSTRACT Few studies have been conducted on the culture of *Nephrops norvegicus* larvae and none of them have permitted significant numbers of postlarvae to be obtained (stage IV). The goal of this study was to determine a suitable diet for rearing *N. norvegicus* to juvenile stage V. Survival, molting periodicity, growth, and elemental composition (CHN) of the young postembryonic stages were used as criteria of physiological condition. Four different diets, fresh enriched nauplii of *Artemia* (FENA), artificial feed for shrimp (AF), commercial frozen mussels (M), and commercial frozen adult *Artemia* (FAA) were tested from hatching to stage V at ambient temperature (14–16 C). Five day old stage I larvae fed with AF, M or FAA showed a similar biomass as freshly hatched larvae, indicating that the energy derived from food only allowed them to survive but not to gain length. FENA was the only diet that resulted in development to stage V. Larvae fed with FENA presented the shortest time of development, the highest rate of survival, and the highest growth rates in size and biomass.

KEY WORDS: *Nephrops*, spiny lobster, larva, growth, diet, C,H,N

INTRODUCTION

The commercial fisheries of the Norway lobster, *Nephrops norvegicus* (Linnaeus, 1758), are economically important in Europe, and many projects regarding this species have been developed with the support of the European Community (ICES 1999, Sardà 1996). In the Mediterranean Sea, the production and average size of *N. norvegicus* have decreased during the past 10 years, while fisheries effort has increased (Franquesa 1996, Lleonart 1995, Sardà 1998a). Growth, reproduction, molt and feeding have recently been studied in the Mediterranean Sea (Sardà 1998b). Despite the economical importance of this species, information concerning the larval stages is scarce compared to that for adults and to other commercial lobster as the species of the genus *Homarus* Weber, 1795. The early postembryonic development consists of three larval stages (I, II, III). These were morphologically described by Sars (1884, 1890) from Norwegian waters, by Jorgensen (1925) from the northeast coast of England, and by Santucci (1926a,b,c, 1927) from the Tyrrhenian Sea. The larval phase is separated by a metamorphic molt from the postlarva (stage IV), which presents the morphological characters of the adult. The postlarvae swim for a few days before becoming benthic. There is still a controversy about the terminology of lobster development; some authors suggest that stage IV is already a juvenile. Others prefer to call stage IV a postlarva or decapodid and stage V the first juvenile (see Phillips & Sastry 1980, Charmantier et al. 1984).

Although larval distribution has been studied in different regions of the Atlantic Ocean and the Mediterranean Sea from a fisheries point of view (Brown et al. 1995, Eiriksson 1970, Farmer 1975, Lindley 1983, Milligan & Nichols 1988, Nichols et al. 1983, Nichols et al. 1987, Thomson et al. 1986), only a few studies have been conducted on requirements for the development of *N. norvegicus* larvae and postlarvae. Figueiredo and Vilela (1972) and Figueiredo (1971) reared *N. norvegicus* larvae in the laboratory at different salinities (33–40‰) and temperatures (7–17°C). In this study, the larvae seemed to be unaffected by salinity in the tested range, while increasing temperature accelerated not only growth, but mortality as well. Larvae reared at 11–14°C presented the highest survival (25% to stage II, 13% to stage III and 7% to stage IV) and juveniles lived as long as three months reaching 18 mm in total length. Increased temperatures also reduced the intermolt period, 14–15 days at 7–10°C to 5–6 days at 13–17°C. *Artemia* Leach, 1819 nauplii proved to be insufficient as a diet and better growth was achieved with eggs of *Crangon crangon* (Linnaeus, 1758) as food. Thompson and Ayers (1989) tested temperatures ranging from 5°C to 15°C finding the same effects as Figueiredo and Vilela (1972) and Figueiredo (1971). The best results were observed at 15°C, where survival was 12% from stage I to stage II, 40% between II and III, and 8% between III and IV. In addition, the estimated duration of the intermolt period was 6.9 days from stage I to stage II, 6.1 days between II and III, and 9.0 days between III and IV. In these studies, small *Artemia* sp. were provided as a food, occasionally complemented with wild plankton and encapsulated feed. Recently, Dickey-Collas et al. (2000), reared *N. norvegicus* larvae at different temperatures from 8.6°C to 14.7°C with a mixed diet of *Tetraselmis suecica* and freshly hatched *Artemia* nauplii. Mortalities were greater than 50% by the end of stage I at all temperatures tested and only one larvae was raised to stage IV at 11.2°C. Stage I lasted from 7 to 18 days and no correlation with the rearing temperature could be made. Survival exceeding 90% to stage III was achieved by feeding the larvae with larger *Artemia* juveniles (Anger & Püschel 1986), but this rearing experiment was not continued thereafter. Development time was 8.7 days for stage I, 11.3 days for stage II, and 11.5 days for stage III. The elemental composition (CHN) of the larvae did not change very much during development. Only freshly hatched larvae showed significantly lower percentages of organic constituents than older larvae.

Hence, further information about the culture conditions of *N. norvegicus* is critical to successful commercial culture. Aquacul-

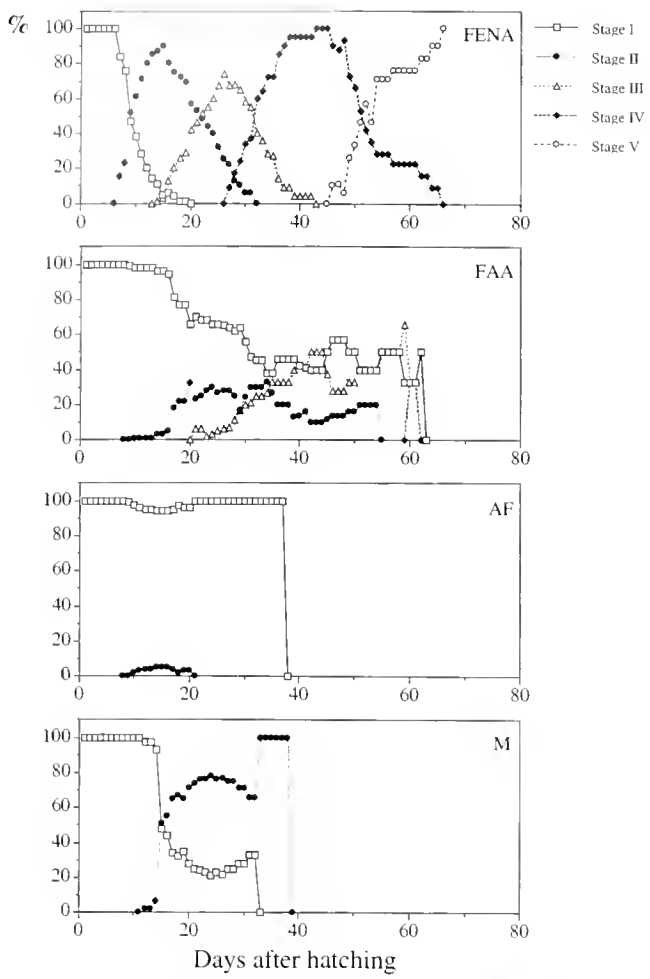

Figure 1. Percent survival and occurrence of successive stages over time for larval and postlarval development of *Nephrops norvegicus* reared with four different diets: fresh enriched nauplii of *Artemia* (FENA— after hatching, nauplii were enriched for 24 h with lipids and vitamins using DHA Selco, INVE); artificial feed for shrimp, DIBAQ (AF); commercial frozen mussels (M); and commercial frozen adult *Artemia* (FAA).

ture of nephropid lobsters has been reviewed by Van Olst et al. (1980), showing that efforts to develop techniques for the culture in controlled environmental systems have been concentrated on species of the genus *Homarus*. By comparison with *N. norvegicus*, a large body of information is now available on the culture and physiology of *Homarus* (review in Factor 1995).

Generally, poor nutritional quality has been shown to increase the time of development and to decrease survival and growth of lobster larvae (Conklin 1995). The goal of the present study was to improve growth, molting, and nutrition of *N. norvegicus* larvae and postlarvae from hatching to stage V, and to evaluate the prospects of a culture to complement the capture fishery.

MATERIALS AND METHODS

Culture of Larvae and Postlarvae

Ovigerous female Norway lobsters were caught off Barcelona harbor by a commercial fishing fleet at 400 m depth from January to March. They were brought to the laboratory and maintained for 1 to 3 weeks in individual cylinder-conic containers protected by a mesh to avoid escape of freshly hatched larvae. These containers were placed in a 3000 L tank with running sea water at a temperature of 15 ± 1°C and 12 h light/12 h dark photoperiod. Females were fed with frozen mussels twice a week.

After hatching, 2,169 larvae from a group of 30 females were cultured individually in connected boxes fed with running seawater at ambient temperature (15 ± 1°C). Four different diets were tested:

1. FENA: fresh enriched nauplii of *Artemia* AF 480 (21.3 mg/g DW HUFA & 0.04 DHA/EPA). After hatching, the nauplii were enriched for 24 h with lipids and vitamins using 300 mg/L of DHA Selco (200 mg/g DW HUFA & 2.96 DHA/EPA) made by INVE AQUACULTURE NV (Oeverstraat 7, 9200 Baasrode, Belgium).
2. FAA: commercial frozen adult *Artemia* produced by Mundo Acuático, S.L. (C/ Llobregós 9, 08032 Barcelona, Spain).
3. AF: artificial feed for shrimp (feed granules of 0.2 mm containing 12% lipids, 15% carbohydrates, 52% proteins, vitamins, oligo-elements, and 5.500 Kcal) produced by DIBAQ AQUACULTURE (Polígono Industrial "Baix Ebre" Parcela 114, Camp-redó, 43897 Tortosa, Spain).
4. M: commercial frozen mussels.

Food was provided *ab libitum* twice a day. The different treatments were applied homogeneously through the circuit boxes in order to ensure that differential mortality was not influenced by the rearing system.

Growth Rate and Molting Frequency

Survival and molting of larvae and postlarvae in each treatment were recorded daily. Carapace length (CL) was measured to the nearest 0.1 mm directly from photographs or with a dissecting microscope for larvae fixed in 4% formol. Carapace length of postlarvae was measured with callipers. Estimates of growth parameters were based on the model of Von Bertalanffy (1938), as this curve has been commonly accepted for adults (e.g. Mytilineou and Sardà 1995, Sardà 1985). For fitting the curve, FISHPARM software was used (Prager et al. 1987). The slopes and intercepts of the different growth curves were compared by applying an ANOVA.

Measurements of Biomass

Larvae from 6 different females were taken immediately after hatching and on day 5 (stage I, intermolt stage C) after feeding with the test diets (FENA, FAA, M, AF). Biomass was measured as wet weight (WW), dry weight (DW), carbon (C), nitrogen (N), and hydrogen (H). The CHN values are presented as absolute (per individual) and relative contents (CHN in % of DW), and as C/N and C/H ratios.

Samples were briefly rinsed in distilled water, blotted on fluff-free filter paper, and WW was measured to the nearest 0.01 mg on an Ohaus AP250D–0 balance. Thereafter, the material was stored at −80°C. Before the analysis, the samples were freeze-dried overnight in a GT 2 (Leybold-Heraeus) apparatus and weighed again to the nearest 0.1 μg on a Mettler UM 3 balance to obtain DW. Larvae were combusted at 1020°C in a CHN analyser (Carlo Erba Science, Model 1108, Version Fisons).

The arithmetic means and the standards errors of biomass were calculated from 4 to 8 replicates. The significance of differences

between mean values of freshly hatched and 5 day old larvae fed different diets were determined using a one-way analysis of variance (ANOVA) followed by a multiple test at a probability level of $p<0.05$.

RESULTS

Molting Frequency

Among the four diets tested, only the FENA diet permitted development to stage V. Commercial frozen adult *artemia* allowed development to stage IV, while AF- and M-fed larvae reached only stage II (Fig. 1). In addition, only larvae fed with FENA showed a regular pattern of molting and development through the successive stages. Commercial frozen adult *Artemia* fed larvae showed a higher rate of survival until day 30 as compared to the other diets. Thereafter, however, the larvae fed with FENA had a slightly higher survival.

Survival and duration of the developmental stages are given in Table 1. Survival rate from stage I to stage II was 21.3% with FENA, 0.9% with AF, 9.4% with M, and 5.4% with FAA. The average time of development from hatching to stage II was 9, 10, 16, and 18 days, respectively, with FENA, AF, M, and FAA. With the two *Artemia* diets, some larvae reached stage IV; the time to reach stages III and IV was 20 and 32 days with FENA, and 30 and 60 days with FAA, respectively.

Growth Rate (Increments in Body Size)

Larvae fed with AF and M survived for up to 40 days, with high variability in length (Fig. 1) and in larval size (carapace length, CL). Larvae and postlarvae fed with FENA or FAA, in contrast, survived for over 70 days (Fig. 1). The Von Bertalanffy growth curves (VBGC) could be fitted only in these two groups (Fig. 2). Their slopes were significantly different ($P<0.001$), showing that the larvae fed with FENA showed a higher rate of growth than those fed with FAA.

Changes in Biomass

Biomass changes (WW, DW, CHN per individual) measured between freshly hatched and 5 day old larvae fed with different diets are documented in Table 2. Changes in the water content (% WW) and in the relative elemental composition (CHN in % of DW; C/N and C/H ratios) are documented in Table 3. Weight and elemental composition (C, N) are shown in Figure 3 for freshly hatched (fh) and 5 day old stage I larvae of one female (no. 23), where sufficient material from all dietary conditions was available.

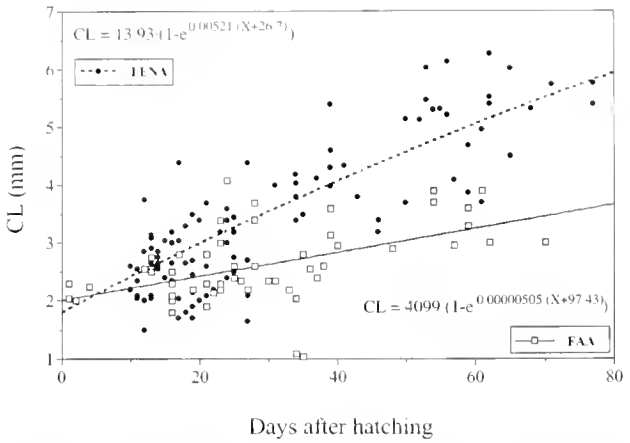

Figure 2. Comparision of Von Berlantanffy growth curves (VBGC) for *Nephrops norvegicus* larvae and postlarvae reared under two different nutritional conditions: fresh enriched nauplii of *Artemia* (FENA) and commercial frozen adult *Artemia* (FAA). See Figure 1 for further details.

This comparison shows that all measures of biomass per individual (WW, DW, C, N; H is not included but shows the same trends) were consistently highest in the FENA group. WW reflected the dietary quality less clearly. Likewise, the percentage CHN figures (in % of DW) were significantly higher in the FENA treatment than in all others. The water content was on average lower in larvae fed with FENA than in the other treatments. In 5 day old FAA-fed larvae, all biomass values were consistently below those of freshly hatched larvae; these losses were statistically significant in the percentage of C, N, and H values (Table 3, Fig. 3).

Hence, FENA was the only diet that allowed the larvae to reach a significantly higher biomass within 5 days of hatching. With FAA, M, and AF, the larvae conserved the initial biomass they already had at hatching but did not gain weight. No significant differences in the C/N and C/H ratios were observed between freshly hatched larvae and those fed for 5 days with any of the test diets. In addition to nutritional effects, significant differences were detected between larvae originating from different females (see Tables 2 and 3).

DISCUSSION

The rate of survival to the juvenile stage V was very low (maximum 0.6%) with all diets. Figueiredo and Vilela (1972) and

FENA: fresh enriched nauplii of *Artemia;* FAA: commercial frozen adult *Artemia;* M: commercial frozen mussel; AF: artificial feed for shrimp.

Thompson and Ayers (1989) found similar rates of survival with a mixed diet (nauplii and adult *Artemia*, wild plankton, or eggs of *Crangon crangon*). However, Anger and Püschel (1986) obtained a survival of over 90% to stage III with living adult *Artemia*, though they did not monitor survival after this stage (considering stage IV as the first juvenile instar). In the present study, FAA-fed larvae showed a high rate of survival through the first 30 days, but the developmental period in stage I was nearly twice that found with other diets in this study or reported by other authors. Also in another clawed lobster, *Homarus americanus* (H. Milne Edwards, 1837), the nutritional value of frozen adult *Artemia* was found to be less than living adult *Artemia* (Conklin 1995). The nutritional value of adult *Artemia* apparently decreases greatly during storage in frozen condition. Figueiredo and Vilela (1972) and Dickey-Collas et al. (2000) showed that early *Artemia* nauplii were also insufficient for *N. norvegicus* larvae, although they were successfully used as a diet for the larvae of palinurid lobsters (Van Olst et al. 1980). The intermolt duration of larvae in stage I was shorter for that fed with FENA. The duration of larva stages fed with FENA was very close to the duration observed by the other authors at similar temperatures (Anger and Püschel 1986, Figueiredo and Vilela 1972, Thompson and Ayers, 1989).

Growth has been studied in *N. norvegicus* adults and juveniles, both in natural populations and in captivity (Belchier et al. 1994, Mytilineou & Sardà 1995, Sardà 1985, Tuck et al. 1997, Verdoit et al. 1999). In the present study, the generally applied Von Bertalanffy (1938) growth curve fit for larvae and postlarvae fed with either FAA or FENA but not for the other treatments. The growth curve obtained with FENA presented a significantly steeper slope, with a CL_∞ value close to 14 mm in the fourth larval stage. Figueiredo and Thomas (1967) found that one year old *N. norvegicus* individuals reach 13–15 mm carapace length, correspond-

FENA: fresh enriched nauplii of *Artemia;* FAA: commercial frozen adult *Artemia;* M: commercial frozen mussel; AF: artificial feed for shrimp.

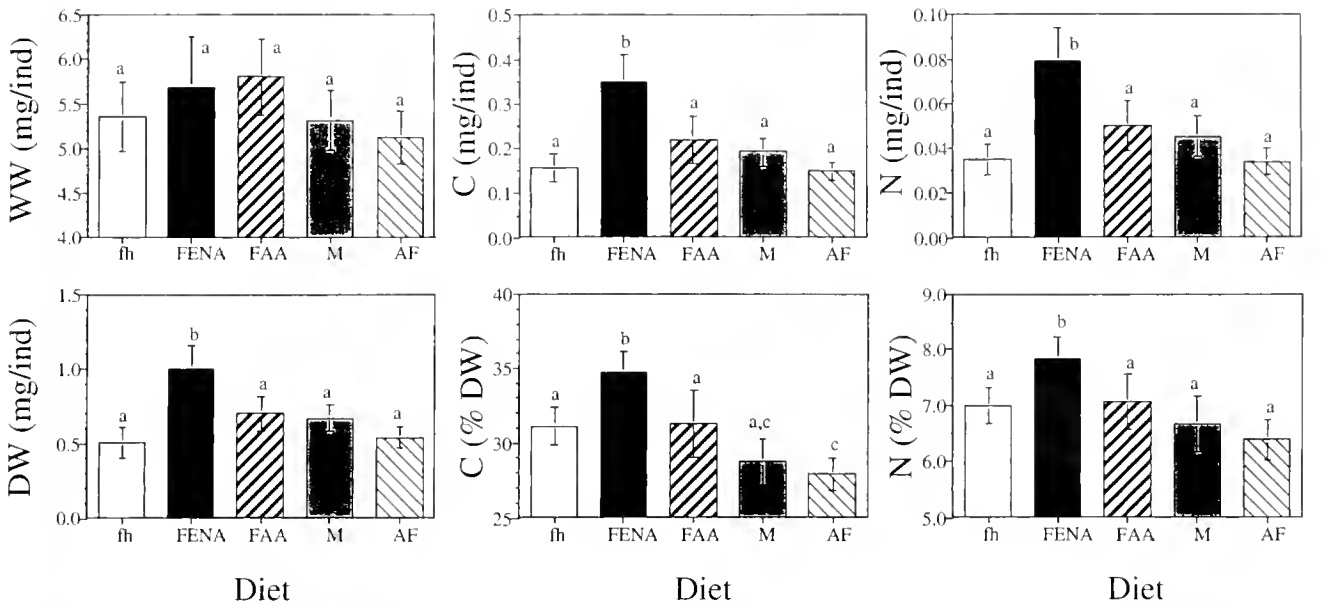

Figure 3. Body composition of freshly hatched (fh) and 5 day old *Nephrops norvegicus* stage-I larvae, reared in the laboratory under 4 different nutritional conditions: fresh enriched nauplii of *Artemia* (FENA); artificial feed for shrimp (AF); commercial frozen mussels (M); and commercial frozen adult *Artemia* (FAA). See Figure 1 for further details. Wet weight (WW), dry weight (DW), Carbon (C), and nitrogen (N) content per individual; C, N also in % of DW.

ing to 20–25 mm total length. Comparing our growth curves for larvae with those obtained by Sardà (1985) for juveniles, we can conclude that the average growth rate of larvae and postlarvae is approximately 4 to 5 times faster than in juveniles.

Feeding in homarid lobsters begins immediately after hatching and the larvae may not recover from nutritional stress if inadequate food is provided during the first stage (Anger et al. 1985, Aiken & Waddy 1995). In the present study, after 5 days of feeding with AF, M, or FAA, stage I *N. norvegicus* larvae showed similar absolute and relative CHN values and a similar water content as freshly hatched larvae. In FENA-fed larvae, by contrast, the CHN contents (both per individual and as proportions of DW) were higher and the water content (in %WW) was lower than at hatching. The CHN values measured by Anger and Püschel (1986) in successfully developing larvae of *N. norvegicus* also increased significantly after hatching. These data indicate that the energy taken from inadequate diets (AF, M, FAA) allowed only for survival but not for gaining length.

In addition, carnivorous larval decapods have limited enzymatic capabilities during the planktonic development. Since a gastric mill is absent, the survival of lobster larvae with the proteolytic enzyme levels must depend upon the high energy, easily-digestible nature of the zooplankton prey, together with an extended gut residence time. In *N. norvegicus* larvae trypsin-like activity and content per individual increases from stage I to stage III (Kumulu and Jones 1997). The CHN results obtained in the present study and the enzymatic works confirm the importance of providing high-quality food immediately after hatching to assure a successful development.

In our data, variation in the C/N and C/H ratios did not reflect the developmental stage or differential nutritional quality of the tested diets. This agrees with observations by Anger and Püschel (1986), who found that the absolute biomass increased significantly during the development of *N. norvegicus* larvae, but the relative composition (CHN in % of ash-free DW) remained fairly constant. Hence, for larvae of this species, the relative composition of CHN seems to be less sensitive as an indicator of the nutritional state than the water content.

N. norvegicus is economically a very important species and its culture is far from being accomplished, particularly when compared with other homarid lobsters. The data presented demonstrates that larvae fed with FENA showed the best nutritional condition. However, future studies in culture systems, water quality, broodstocks, and feeding are necessary to improve Norway lobster larval development.

ACKNOWLEDGMENTS

The authors thank Ms. C. Püschel, G. Fuster, C. García and J. Riba for technical support, Dr. L. Recasens for her help in the growth studies, the Captains and crews of the fishing vessels Maireta III, Francesc i Lluis, and Zorrilla from Barcelona harbor, and Ms. Lluís Boix (DIBAQ AQUACULTURE) for donating commercial artificial food for shrimps. This study was supported by a joint grant from the Catalonian (Spain) and Languedoc-Roussillon (French) Communities and by the "Centre de Referència de Recerca i Desenvolupament en Aqüicultura de la Generalitat de Catalunya."

WIND PATTERN MAY EXPLAIN THE SOUTHERN LIMIT OF DISTRIBUTION OF A SOUTHWESTERN ATLANTIC FIDDLER CRAB

EUGENIA BOGAZZI,[1,2,*] OSCAR IRIBARNE,[1,3] RAUL GUERRERO,[1,2] EDUARDO SPIVAK[1]

[1]Universidad Nacional de Mar del Plata, Departamento de Biología (FCEyN), CC 573 Correo Central (7600) Mar del Plata, Argentina; [2]Instituto Nacional de Investigación y Desarrollo Pesquero, Victoria Ocampo N 1, CC 175, (7600) Mar del Plata, Argentina; [3]CONICET, Argentina

ABSTRACT The SW Atlantic fiddler crab *Uca uruguayensis* (Nobili 1901) is distributed from the northern limit of the Argentinean Biogeographic Province (31°S to 42°S) to the northern part of Argentina (38°34′S). This distribution range seem puzzling given that this biogeographic province goes several hundred kilometers S and there are no obvious environmental discontinuities that might explain this pattern. To explore possible causes of this distribution, hypotheses related to biological and oceanographic constraints were investigated. A comparative study between the three southern sites (Bahía Samborombón, 35°30′–36°22′S; Mar Chiquita coastal lagoon, 37°46′S and Quequén Grande river, 38°34′S) where this species inhabits showed that biological constraints are not the limiting factor. There were no differences in morphometry, reproductive timing and output, body condition and larval sizes. Differences were only found on the size frequency distributions, which indicate differences in recruitment regularity. However, wind patterns relative to coastal bearings indicate that during the period of larval release and recruitment (December to April), the contribution of wind drift transport are less frequently coastward from the La Plata river (35°–36°20′S, where Samborombón is located) to the south. If the wind stress is the main force moving the upper layer of the water column and consequently crab larvae, then this pattern would indicate that there is a decrease in the chances of carrying megalopae to the coast south of the La Plata river. On the basis of this information we suggest that the southern distribution limits of this species is mainly due to wind pattern.

KEY WORDS: fiddler crabs, *Uca uruguayensis*, distribution, recruitment, wind pattern, larval supply

INTRODUCTION

The Argentinean Biogeographic Province is an homogeneous area with regards to pelagic and offshore inhabiting species (see Balech 1964, Bernasconi 1964, Stuardo 1964, Menni and Gosztonyi 1982, Boschi 2000). The southwestern Atlantic waters in this area are transitional between colder subantarctic and warmer subtropical Brazilian waters (Longhurst 1998).

The southwestern Atlantic fiddler crab *Uca uruguayensis* (Nobili 1901) is found from southern Brazil (33°S) to the northern coast of Argentina (38°S; Boschi 1964) in estuarine environments, overpassing the La Plata river (35°–36°20′S) but not reaching the southern limit of the biogeographic province. One of the southernmost permanent populations inhabits Bahía Samborombón (35°30′–36°22′S) where it is the dominant intertidal species (Boschi 1964) reaching densities of up to 140 crabs m^{-2} (Iribarne and Martinez 1999). Smaller populations are found a few hundred kilometers south, at the Mar Chiquita coastal lagoon (37°46′S, 57°27′W; Spivak et al. 1991), at the Quequén Grande estuary (38°34′S; Boschi et al. 1992) and at the Quequén Salado estuary (38°56′S; pers. obs.; Fig. 1). This distribution pattern seems puzzling, given the lack of obvious environmental features (e.g., large rivers or obvious changes in current pattern) that may explain it. However, even when the causes are unknown the processes that determine this pattern should be either biological limitations (e.g., McConaugha 1992) or physical factors affecting larval distribution (e.g., Roughgarden et al. 1988). The main purpose of this work is to explore these alternative hypotheses.

Several authors have discussed the existence of limitations in the species distribution (see Hengeveld 1992), particularly in species with dispersion through larvae. Geographic distribution can be limited by biological factors (e.g., Menge 1991), hydrographic processes that modify the supply of larvae (e.g., Farrell et al. 1991), relationship between these two options (e.g., Connolly & Roughgarden 1998) or environmental factors such as air temperature, tidal range, rainfall (Crane 1975) and sediment characteristic (Frith & Brunenmeister 1980).

Some *Uca* species produce planktonic larvae that are exported to open ocean and then return to recolonize their habitats (Lambert and Epifanio 1982, Epifanio 1988). Success of recruitment depends on larval survival in the planktonic phase and subsequent settlement in the adult habitat (McConaugha 1992), which may largely depend on nearshore hydrodynamic processes (Underwood & Denley 1984, Farrell et al. 1991). On the basis of a comparative analysis between the three southernmost populations as well as wind field analysis on several years, as the most possible factor responsible of coastal circulation, the purpose of this work is to investigate this general hypothesis. Specifically, we state and explore two sets of hypothesis that may explain the southern distribution limit of this species: (a) biological limitation and (b) oceanographic constraints.

MATERIALS AND METHODS

Study Sites

The study was conducted in three sites (Fig. 1): (1) the mouth of the easternmost tidal channel (San Clemente tidal inlet;

*Corresponding author. Instituto Nacional de Investigación y Desarrollo Pesquero, Victoria Ocampo N 1, CC 175, (7600) Mar del Plata, Argentina. E-mail: ebogazzi@inidep.edu.ar

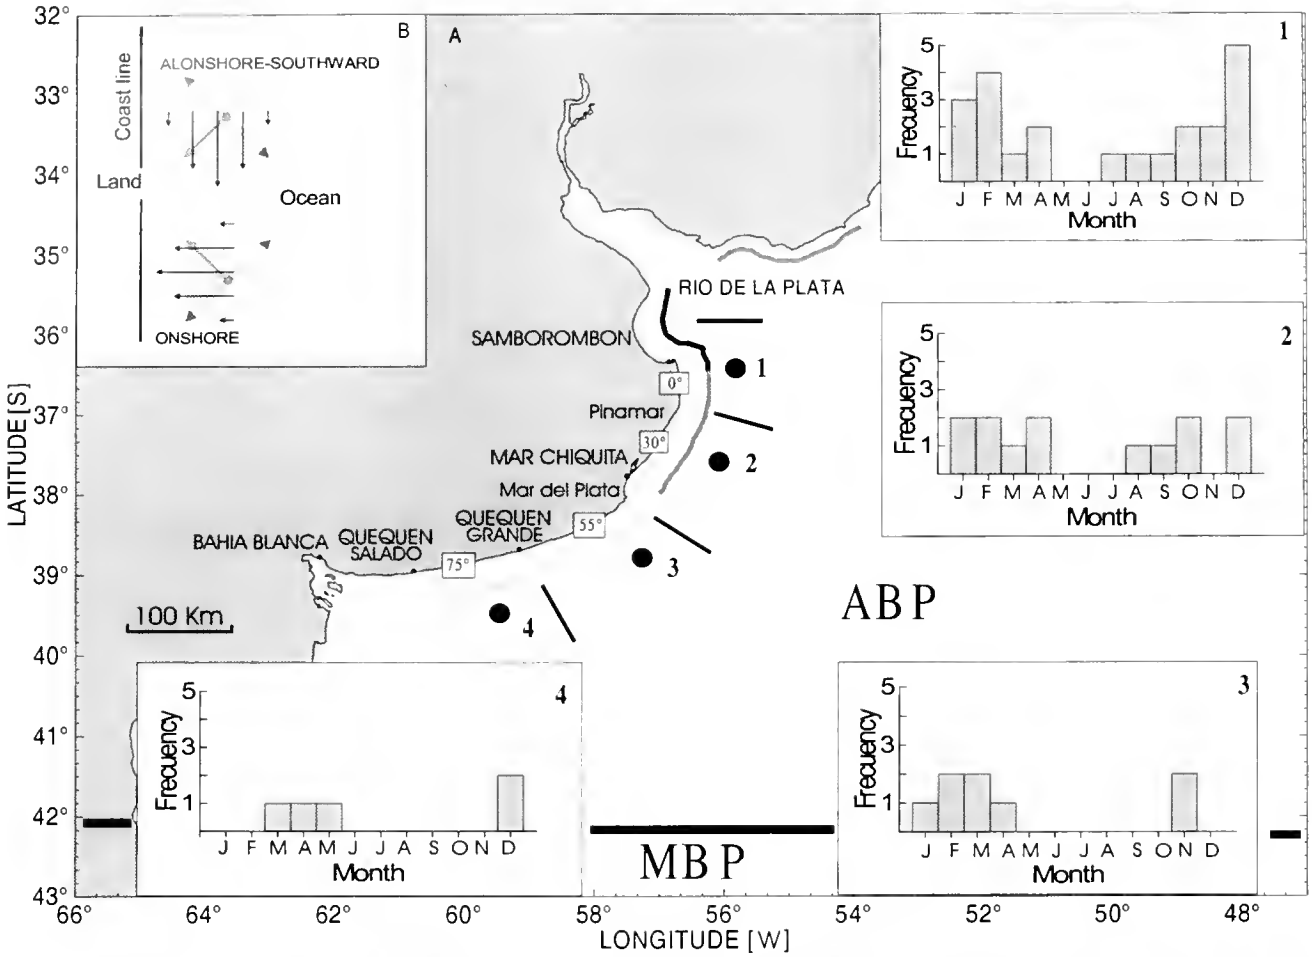

Figure 1. (A) Geographic position of the study sites: Samborombón bay, Mar Chiquita coastal lagoon, Quequén Grande river, Quequén Salado river. Line along the coast represents geographic distribution of *Uca uruguayensis*. ABP: Argentinean Biogeographic Province, MBP: Magellanic Biogeographic Province. Grid points position for the MWF data analyzed (1 to 4). Solid lines delimit the four areas according to coastal bearing. (B) Ekman surface layer field current (dark arrows) forced by wind field (background arrows) that gives favorable drift (southward and onshore) contributing to the megalopae recruitment. Histograms 1 to 4 correspond to monthly occurrence (absolute number of records) of southward and onshore conditions during the time period analyzed.

36°22′S, 56°45′W) of the Bahía Samborombón (100 km long coastal basin within La Plata river estuary, Argentina), (2) the Mar Chiquita coastal lagoon (37°46′S; 300 km south), and (3) Quequén Grande estuary of the river (38°34′S; 200 km further south). All areas are characterized by fiddler crabs (*Uca uruguayensis*) and burrowing crabs (*Chasmagnathus granulata*) populations (Spivak et al. 1991, Iribarne and Martinez 1999). The littoral zone extends into an extensive *Spartina*-dominated saltmarsh (Bortolus and Iribarne 1999) and the fiddler crab population inhabits the upper open intertidal zone near the *Spartina densiflora* fringe, with few individuals living at vegetated areas. Information was also obtained from Quequén Salado river (38°56′S.) a site located 150 Km west of the Quequén Grande river.

Biological Characteristics

Crab samples were collected monthly from October 1998 to February 1999, covering the reproductive season (see Spivak et al. 1991). Each time, a random sample of 100 individuals was obtained to evaluate size frequency distribution, sex ratio and reproductive stage. Given that distribution of this species is patchy, to estimate density from each study site we obtained 50 sampling units of 1 m^2, 10 m apart, covering 500 m along the coast. Within dense patches (clearly noticeable crab beds) also 10 samples were obtained using the same procedure. Both sampling schemes were intended to have a measure of the mean overall density (density along the whole beach) and mean density of the *Uca* beds. ANOVA tests were used to evaluate differences between sites for both sampling strategies (Zar 1999).

Given logistic constraints, it was impossible to keep track of settlement and recruitment across the southern boundary. Therefore, for each study site, size frequency distribution as well as diverse population and individual characteristics were evaluated to consider possible post-recruitment process that could produce the latitudinal abundance failure.

From each sample, number of males and, ovigerous and non-ovigerous females were counted. All individuals were measured (maximum carapace width, precision 0.02 mm). Comparing crab body conditions from different sites, male and female (non-ovigerous and ovigerous without eggs) dry weight were considered covering homogeneously size classes found at each site. Crabs

were dried at 70 C during 48 hours, and weighed (precision 0.001 g). The null hypothesis of no difference in the relationship between dry weight and crab size, among categories (i.e., males, non-ovigerous females and ovigerous females) and sites, was evaluated with an ANCOVA test (Neter et al. 1990).

To compare the amount of energy allocated to reproduction between sites, carbon proportion (as ash free dry weight, AFDW) between the egg masses and the females body (without eggs) was estimated. This proportion was called "energetic allocation". AFDW was obtained by incinerating the samples at 500°C for 4 hours, after having them drying for 48 hours at 70°C. We first evaluated the relationship between "energetic allocation" and female size; given the lack of relationship we just tested the null hypothesis of no difference in the mean values using Kruskall-Wallis test (Zar 1999).

To compare egg production between sites, eggs number were estimated from dry weight of the egg mass (precision 0.0001 g) weighing 500 eggs from each site. Two egg stages were defined: "early", when embryo were undifferentiated and the eggs were completely filled with vitellum, and "late" when embryo is differentiated, with eyes and the egg was less than 40% filled with vitellum. The null hypothesis of no difference in the relationship between carapace width and number of eggs among sites was evaluated with an ANCOVA test (Neter et al. 1990). To evaluate differences between number of early and late stage eggs for each site, the average egg mortality during development was estimated. The null hypothesis of no difference was evaluated with an ANCOVA test (Neter et al. 1990).

Early stage eggs from at least 50 females (regardless of carapace width) from each site were sampled, measuring their maximum length with an ocular micrometer (precision 0.01 mm). The null hypothesis of no difference among sites was evaluated with a Kolmogorov-Smirnov test (Conover 1980).

Morphometric characteristics were evaluated in order to examine possible phenotypic plasticity. Different body measures were also obtained from males and females from each site (50 each), in order to perform a whole morphometric comparison. From each individual we measured: (1) carapace length (CL), (2) maximum carapace width (CW), (3) minimum carapace width (MCW), (4) distance between eyes (DE) (5) merus length of the third pereiopod of the left side of females and the hypertrophied side of males (Lp1), (6) width of the fourth segment of the abdomen (AW), and (7) corporal height (CH). For males, we also obtained several measures of the hypertrophied cheliped: (8) merus length (ML), (9) carpus length (CLC), (10) total propodus length (PL), (k) propodus width (PW), (11) propodus height (PH), and (12) dactylus length (DL). Individuals of similar sizes were selected from each site to avoid the effect of size. Data were log transformed to comply with statistical analysis assumptions (Hair et al. 1995).

Sizes and morphometry of larvae were also analyzed. Five females from two extreme sampling sites (Samborombón and Quequén) were maintained in aquarium with seawater salinity of 34 at continuous aeration (following Rieger 1996). When eggs hatched, 50 larvae (zoea I) were preserved in 3% formalin. Then, the following measures were obtained: (1) total rostral length (RL), (2) frontal spine length (FSL), (3) dorsal spine total length of the (DSL) and (4) carapace length (CL). All measures were obtained with a precision of 0.02 mm. Then a discriminant analysis (DFA) (Hair et al. 1995) of both larvae and adults, was performed independently to evaluate the null hypothesis of no differences between sites.

Wind Pattern

Wind-driven coastal circulation estimated as Ekman (1905) transport was assumed to be responsible for larval transport in coastal areas (McConnaughey et al. 1992). Ocean surface monthly mean winds (Mean Wind Field, MWF) from ERS-1, ERS-2 and ADEOS-1 scatterometers database (IFREMER 1998) were employed in this analysis to infer Ekman transport. The period covered was from August 1991-February 1998, totaling 78 observations (lacking February 1992). Monthly winds were statistical interpolated using kriging minimal variance method and integrated into objective analysis (Bentamy et al. 1996) to obtain the monthly mean. Each grid points used on this analysis had an average of 8.6 satellite observations (SD = 3.6). Grid spatial resolution was 1° × 1° in latitude and longitude (111 km × 92.5 km average for study region). Accuracy reported for ERS scatterometer wind data was analyzed by comparison with *in-situ* measurements from the National Buoy Data Center, Tropical Atmosphere Ocean data and Japan Meteorological Agency buoy data (Graber et al. 1996). The root square mean error was 1.2 m s^{-1} in intensity and 24° in direction (Graber et al. 1996). NSCAT / ERS-2 correlation shown error differences about 1.1 m s^{-1} and up to 28° (IFREMER 1998).

Direction of the Ekman transport (Ekman 1905, cited by Neumann & Pierson 1966) forced by these winds was estimated at selected grid points of study area (Fig. 1A) to evaluate favorable larval drift. For the southern hemisphere the direction of pure drift current at the surface will result 45° to the left of wind vector, while the vertical integrated transport over Ekman layer will be 90° to left of the wind direction. These angles will start decreasing when water depth diminishes below 40 m where the frictional layer reaches the bottom. For this study, we considered that the transport of the upper surface layer will result 45° to the left of the wind direction taking into account the water depth off the coast ranges mostly between 30 to 50 m. This assumption was also coherent with observations on *Cancer magister* zoeae and megalopae drift off Northeastern Pacific (Lough 1976, Reilly 1983) and was applied by McConnaughey et al. (1992) on *C. magister* recruitment variability studies.

Winds were assembled by the direction of the resulting surface flow into four groups of 180° angle range, where each would force the upper water layer to have, relative to coastline, an onshore or offshore and southward or northward component. For a 0° coastline oriented N-S, an onshore (offshore) condition will result when wind blows from 45° to 225° (225° to 45°), with maximum effect with SE winds or 135° (NW or 315°; Fig. 1B). Southward (northward) flow will occur under winds blowing from the angle range 315° to 135° (135° to 315°), with an optimum displacement with NE winds or 45° (SW or 225°). Four coastal regions were associated to each grid point, where wind directions were broken down relative to a defined coastal bearing (Fig. 1A): (1) Samborombón-Pinamar (37°07′S, 57°10′W) 0° angle; (2) Pinamar-Mar del Plata 30° angle; (3) Mar del Plata-Quequén Grande 55° angle and (4) west of Quequén Grande 75° angle. Favorable *Uca uruguayensis* settlement was considered when winds force upper surface waters to move onshore and in a southward direction. For each region the wind directions that favor this drift condition were plotted throughout the year (insert 1 to 4 on Fig. 1). To a pool of absolute number of events recorded from December to April, the null hypothesis of no difference between regions in the proportion favorable:non favorable events was evaluated with multiple comparisons for proportions (Zar 1999).

Results

Biological Characteristics

Maximum density showed differences between Samborombón and two other sites (ANOVA: F = 61.98, df = 1, 33; *a posteriori* Tukey analysis $P < 0.01$). The mean density showed a latitudinal gradient, being higher at Samborombón, intermediate at Mar Chiquita and lower at both Quequén river sites (Kruskall-Wallis: H = 51.075, df = 3, 263, $P < 0.01$), no differences between Quequén Grande and Quequén Salado were found (Fig. 2).

Size frequency distribution differences between sexes were found at Quequén (Fig. 3) where males were larger. Those males were also larger than males at the two other sampled sites (Samborombón: x = 10.52 mm, SD = 1.82; Mar Chiquita: x = 10.72 mm, SD = 1.82; Quequén: x = 12.15 mm, SD = 0.89). Females of Samborombón were smaller than those from the other two sites (Samborombón: x = 9.79 mm, SD = 1.38; Mar Chiquita: x = 11.09 mm, SD = 1.22; Quequén: x = 10.95 mm, SD = 1.13).

Male proportion was higher at all sites (Samborombón: 41.7f: 58.3m ($P < 0.01$), Mar Chiquita: 36.3f:63.7m ($P < 0.05$), Quequén: 34.8f:65.2m ($P < 0.01$)), but there were no differences between sites (F = 2.14, df = 2, 526, $P > 0.05$). Although some differences were found, ovigerous female percentages showed a similar pattern through the summer at all sites (Fig. 4).

At all sites, differences in dry weight and carapace width relation between sexes were found, being higher in males and smaller in ovigerous females (Samborombón: ANCOVA: F = 105.2, df = 2, 145, $P < 0.01$; Mar Chiquita: ANCOVA: F = 31.7, df = 2, 72, $P < 0.01$; Quequén: ANCOVA: F = 80.3, df = 2, 132, $P < 0.01$; Tukey *a posteriori*, always $P < 0.01$; Fig. 5). Regarding slope, only differences were found between sites for males, being lower at Samborombón (Regression Analysis for log transformed data: Samborombón: F = 85.3, df = 47, b = 0.09, $P < 0.01$; Mar Chiquita: F = 448.1, df = 30, b = 0.14, $P < 0.01$; Quequén: F = 160.7, df = 31, b = 0.14, $P < 0.01$). High heteroscedasticity for males at Mar Chiquita and Quequén did not allow comparison. Females showed no difference between sites in slope. ANCOVA analysis showed differences in ovigerous females between sites (non-ovigerous females: F = 2.18, df = 1, 127, $P > 0.05$; ovigerous females: F = 11.15, df = 1, 118, $P < 0.01$) which were higher at Quequén (Tukey *a posteriori* test: Samborombón-Mar Chiquita: $P > 0.05$, Samborombón-Quequén: $P < 0.01$, Mar Chiquita-Quequén: $P < 0.01$).

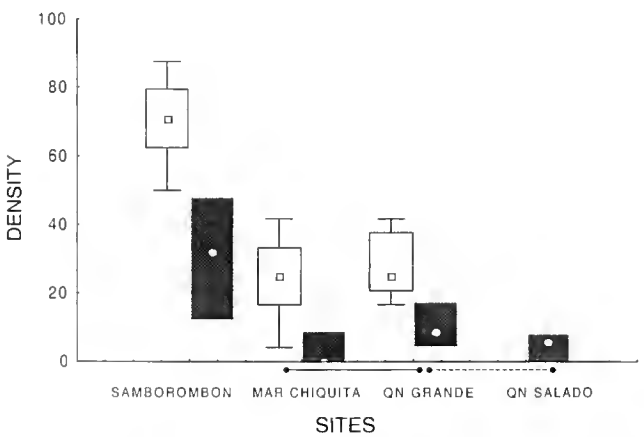

Figure 2. Density expressed as crabs m^{-2} within dense patches (MAXIMUM) and along 500 m of the coast (MEAN). Box plots are constructed with limits of boxes being the 75th and 25th percentile; lines represent 10th and 90th percentiles. Points inside boxes are medians. Boxes underlined are not significantly different between sites (ANOVA-Tukey test, $P > 0.05$; To MEAN: Kruskall-Wallis test, $P > 0.05$). Solid box: maximum density and dashed box: mean density.

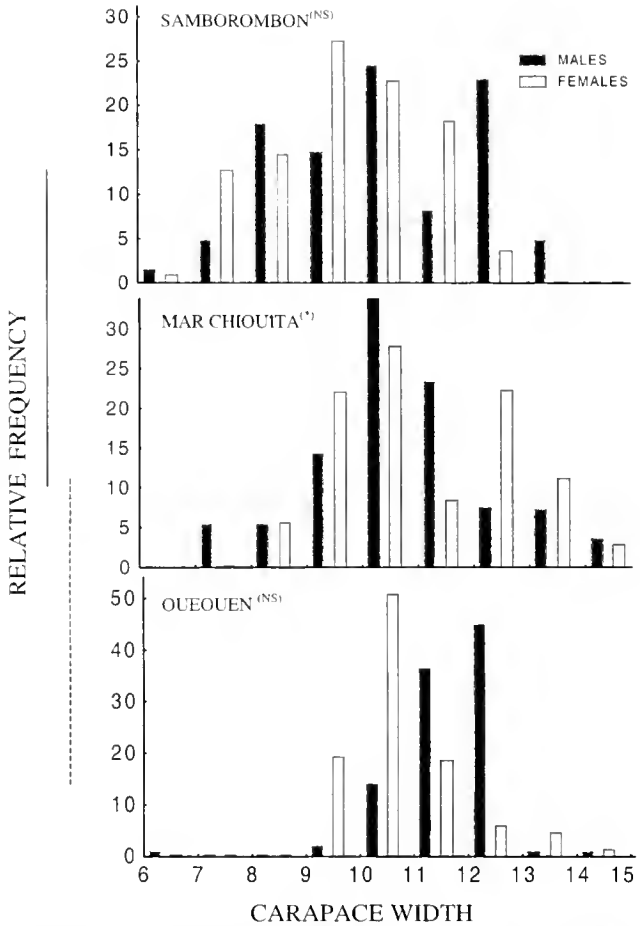

Figure 3. Size frequency distributions (carapace width, mm) of males and females, for each site. Relative frequency is the percentage of crabs of the total sample. Vertical lines parallel to axis indicate no significant difference between sites (Kolmogorov- Smirnov test, $P > 0.05$). Results of Kolmogorov-Smirnov test between sexes are indicated by: (*) $P < 0.01$ and (NS): $P > 0.05$.

There was no relationship between carapace width and energetic allocation at any site (Samborombón: t = −1.32, df = 60, $r^2 = 0.029$, pe = 1.31, $P > 0.05$; Mar Chiquita: t = 0.55, df = 23, $r^2 = 0.014$, pe = 0.88, $P > 0.05$; Quequén: t = -0.45, df = 60, $r^2 = 0.003$, pe = 1.06, $P > 0.05$). There were no differences between sites in AFDW (Kruskal-Wallis: $\chi^2 = 3.8$, df = 2, 141, $P > 0.05$).

There were no differences between sites in the relationship between female carapace width and egg number (ANCOVA: F = 1.9, df = 2, 143, $P > 0.05$ Fig. 6). Egg size was not correlated with female size at any site. The early egg size frequency distribution showed smaller sizes in Mar Chiquita (Kolmogorov-Smirnov test: Samborombón-Mar Chiquita: $P < 0.01$, Samborombón-Quequén: $P > 0.05$, Mar Chiquita-Quequén: $P < 0.01$). The relationship between female carapace width and egg numbers did not show significant egg mortality at both sites (between egg stages, Samborombón: ANCOVA: F = 0.098, df = 1, 46, $P > 0.05$; Quequén: ANCOVA: F = 0.58, df = 1, 57, $P > 0.05$).

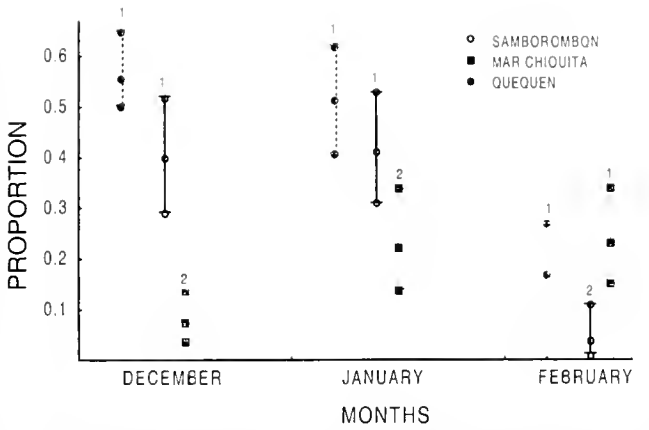

Figure 4. Proportion of ovigerous to non-ovigerous females (Ho/H) along reproductive period (December 1998 to February 1999), for each site. Relative frequency is the percentage of crabs with respect to total sample. Different numbers indicate differences between sites at $P < 0.05$ (Non-parametric multiple comparison test, NS: $P > 0.05$; Zar 1999). Segments indicates confidence limits for the proportion of ovigerous females:non-ovigerous females, for each site and month (Zar 1999).

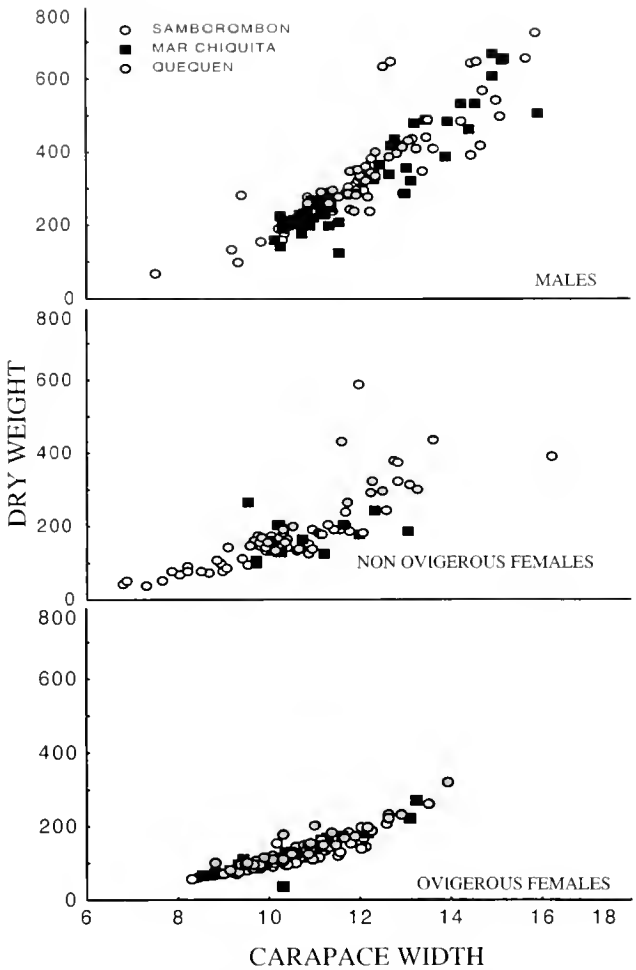

Figure 5. Relationships between size (carapace width, mm) and dry weight (mg) of males, non-ovigerous females and ovigerous females, for each site.

The discriminant analysis was unable to discriminate between different groups of *Uca uruguayensis* regardless of their geographical origin (DFA, log transformed: Males: Lambda Wilk = 0.36, F = 1.65, df = 22, 54, $P > 0.05$; Females: Lambda Wilk = 0.75, F = 1.48, df = 12, 114, $P > 0.05$). All morphometric characters had some contribution to variance, being DL and PH and CW and MCW the variable with the higher weight to males and females, respectively. Larvae discriminant analysis did not either show significant differences between sites (DFA: Lambda Wilk = 0.83, F = 2.14, df = 4, 41, $P > 0.05$). However, some differences may occur given that individuals were classified 85.2% at Samborombón while only 42.1% those from Quequén.

Wind Patterns

On the basis of satellite imagery, wind patterns that drive surface water southward and onshore were observed in the late spring and summer periods for four regions. However, these favorable conditions did not occur every year, and inter-annual variability is important. From the 46 months analyzed (from December to April) 15, 9, 6 and 4 months were favorable at 1, 2, 3, and 4 regions, respectively. There was no significant difference in proportion (favorable:non favorable events) between regions 2 and 3, and 3 and 4 (Multiple comparison for proportions: region 2:region 3, $P > 0.05$; region 3:region 4, $P > 0.05$; insert 1 to 4 on Fig. 1). Characteristic mean wind module with favorable directions for regions 1 and 2 was 6.3 m s^{-1} (SD = 0.8 m s^{-1}).

DISCUSSION

Our results show a clear pattern of decreasing density and abundance of *Uca uruguayensis* with latitude over a land distance of less than 300 kilometers. However, there are no evidences of biological differences. Reproduction shows a similar pattern, fecundity is not different, eggs and larval sizes as well as the amount of energy allocated to eggs are similar. Only a difference in large adult size frequency distribution is found.

Differences in size frequency distribution may be due to recruitment or survival, genetic differences (Hartnoll et al. 1993), food availability (Genoni 1985) and/or quality differences or food competition. Higher density at Samborombón may increase food competition and affect growth rate. Indeed lower body condition (as reflected in dry weight pattern) shown may be the result of higher density. Males and ovigerous females are individuals that require high energetic reserves (Klaassen & Ens 1993). However, better body condition found on females at the southern limit of distribution suggests that the decrease in abundance is not due to physiological constraints. Furthermore, morphometric results did not show geographic differences, suggesting that environmental condition (including diet, habitat etc.) would not be differencing phenotypic expression between sites (see Overton et al. 1997).

Sediment characteristics, organic content or humidity are recognized as important factors in determining *Uca* species distribution (e.g., Teal 1958). However the comparison of the burrowing crab effect on sediment characteristics, between Mar Chiquita and Samborombón, reveal that there are no differences in the sediment properties (Botto and Iribarne 2000), and suggests that these factors are not the basis for the density differences between sites.

Predation by shorebirds has only been observed at Samborombón (Iribarne and Martinez 1999), although other sites such as Mar Chiquita are well studied (Botto et al. 1998; Botto et al. 2000). There are four migratory shorebirds (*Pluvialis squatarola, P. dominica, Numenius phaeopus* and *Arenaria interpres*) and a tern

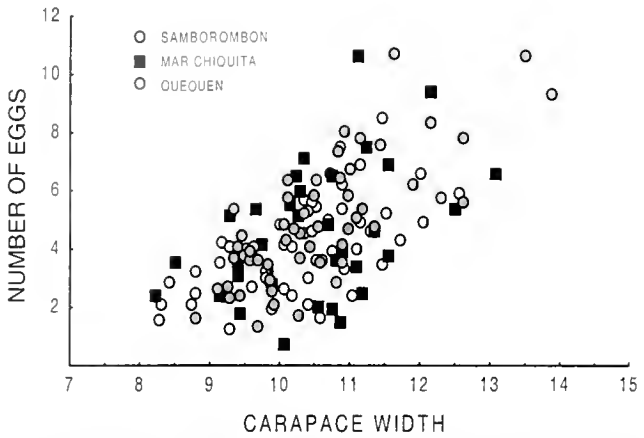

Figure 6. Relationships between number of eggs (in thousands) and carapace width (mm) of ovigerous females. For each site data of egg stage (early, late) and month (December, January, February) were pooled.

(*Gelochelydon nilotica*) that heavily prey on fiddler crabs at Bahía Samborombón, but not at the other sites (Iribarne and Martinez 1999). Although this strong predation pressure may explain small sizes at Samborombón, it does not explain the southern limit of the distribution.

Size frequency distribution at Mar Chiquita and Quequén show absence of individual corresponding to early autumn recruitment (from 5 to 7 mm, see Spivak et al. 1991). All information previously discussed does not explain such difference with Samborombón nor the latitudinal gradient density. An alternative explanation can be based on low temperature effect on post-recruitment mortality. This hypothesis is based on: (1) the fact that species of *Uca* are known to be tropical (Crane 1975) and (2) its temperature range tolerance is low (see Dezi et al. 1993, Vernberg and Tashian 1959). Although temperature can limit *Uca* species latitudinal distribution, limitations of land crab distributions by low temperature does not need to involve mass mortality since cold can limit energy available for growth (Wolcott 1988). Pattern of annual temperature suggests that during winter months the higher latitude sites seem to have a relatively lower minimum (4.7°C at Quequén and 4.8°C at Bahía Blanca, 38°43′S; Anonymous 1985, 1992); however, differences appear to be very small to support such hypothesis (maximum difference 2.7°C, between Samborombón and Quequén).

An alternative hypothesis, but not independent, is the lack of supply of larvae to the south. Larvae fate is unknown in this species, though in most *Uca* species they are exported to sea and will reinvade estuary sometime later (Lambert and Epifanio 1982; Epifanio 1988). Generally, larval movement can be entirely at mercy of currents (Butman 1987). As a consequence, larvae of coastal organisms can be transported by nearshore currents hundred of kilometers (Bertness 1999). The return of postlarvae (i.e., megalopae) to the estuary may be the problem. Settlement and recruitment process are recognized as important in determining the distribution and abundance of species ("supply side ecology": i.e., Lewin 1986) especially for benthic marine invertebrates where new individuals are supplied through settlement of pelagic larvae (Gaines and Roughgarden 1985). In this case, population size may be limited by the arrival rate of larvae. Such "recruitment limited" populations would fluctuate in size as a response to temporal fluctuations in larval settlement rate. As a result, recruitment limited populations could be defined empirically as those with significant temporal correlation between settlement rates and local population sizes (Gaines and Lafferty 1995).

In metapopulational context, larvae local populations contribute to a common larval pool, from where they are subsequently distributed among local populations (Roughgarden and Iwasa 1986). Larval transport among local populations is a function of the physics of ocean circulation, larvae behavior and duration of planktonic stages (see Gaines and Lafferty 1995). Particularly, wind forced currents have been shown to play an important role in larval transport shoreward for settlement at the appropriate time (e.g., acorn barnacles *Semibalanus balanoides:* Hawkins and Hartnoll 1982; bryozoan *Membranipora membranacea*: Yoshioka 1982; blue crab *Callinectes sapidus*: Johnson and Hester 1989). Thus, if recruitment of megalopae to the estuary depends on transport forced by nearshore wind patterns, the supply of adults would also be affected by variations in the yearly wind pattern during the critical time when larvae are offshore (Johnson and Hester 1989). Our work evaluated the year round pattern of winds driving a southward and onshore Ekman drift. During late spring and summer the larvae may reside offshore in the surface water and are affected mainly by Ekman transport due to wind stress. This phenomenon is observed for other species (e.g., American lobster *Homarus americanus*: Campbell 1989; *Callinectes sapidus:* Johnson and Hester 1989; Dungeness crab *Cancer magister:* McConnaughey et al. 1992). Wind transport influences *Uca* spp megalopae on larger open bodies of water, whereas tidal events become more important regarding the entry to the estuary (Mense et al. 1995).

Our evidence based on wind patterns suggests that supply of larvae is the limiting factor, although the coupling of the coastal ocean and marine atmosphere (exchanging buoyancy and momentum) occurs within a time scale of a week (synoptic signal). With 1-month resolution, a general trend is still observed. Synoptic signal inclusion in wind monthly mean is confirmed through the comparison between twelve months from 1993 database used, and simulated monthly mean linearly interpolated from synoptic European Center for Medium-Range Weather Forecasts analysis (ECMWF) shows that both data set are correlated between latitude 60°S to 60°N. Correlation coefficient value changes with latitude, but for the study region it is between 0.4 and 0.8 ($P < 0.05$; IFREMER 1998).

Our results show that wind condition in the coastal zone (southward and onshore) provides more favorable conditions to settlement at the northern sector of the study area than at the southern estuaries. This pattern agrees with a latitudinal decrease in *Uca* densities from Samborombón to Quequén. Recruitment (as inferred from the size frequency distribution) also is continuous at Samborombón (Iribarne and Martinez 1999), while it is not evident at southern estuaries. Ancillary information on recruitment between 1993 and 1996 at Mar Chiquita coastal lagoon (Luppi pers. obs.) shows that settlement success agrees with coastward wind pattern inferred from monthly estimates. These data show that recruitment success was high only in January 1996 (at least 39 megalopae m^{-2}), intermediate in March 1993 (21 megalopae m^{-2}), and low in January 1995 (2 megalopae m^{-2}) and March 1994 (8 megalopae m^{-2}). Furthermore, during the summer 1997 megalopae were found sporadically (Valero et al. 1999). This information coincides with favorable (1996) and unfavorable wind pattern conditions (for other years). Thus, abundance pattern is consistent with latitudinal gradient in the larvae arrival hypothesis, rather than unfavorable environmental conditions for the biology of this species. Furthermore, on the basis of results it is likely that Sam-

borombón acts as the parental stock while the other are 'satellite' populations (Hanski 1982).

EFFECT OF BROODSTOCK DIET ON REPRODUCTIVE PERFORMANCE OF THE PEPPERMINT SHRIMP, *LYSMATA WURDEMANNI*

JUNDA LIN* AND DONG ZHANG

Department of Biological Sciences, Florida Institute of Technology, Melbourne, Florida 32901

ABSTRACT Four types of frozen adult *Artemia* biomass [regular and enriched (with HUFAS and other nutritional supplements) San Francisco Bay and Canadian brands], and frozen hard clam (*Mercenaria mercenaria*) were evaluated as broodstock diet for the marine ornamental shrimp *Lysmata wurdemanni*. There is no significant difference among the five diet treatments in fecundity (number of eggs produced), relative fecundity (number of eggs/g female), egg dry weight, egg percent ash, and total length of newly hatched larvae. Egg volume was significantly larger in the San Francisco Bay regular treatment than those of other treatments. Survivorship from zoea 1 to zoea 2 was higher in the San Francisco regular, Canada enriched, and hard clam treatments.

KEY WORDS: Broodstock diet, *Lysmata wurdemanni*, ornamental shrimp, reproductive performance

INTRODUCTION

Practically all of the marine organisms marketed in the aquarium trade industry are collected from coral reef ecosystems. Extensive and destructive collection has caused great concerns and much efforts have been devoted to develop technologies to cultivate these species. Peppermint shrimp, *Lysmata wurdemanni*, is one of the most popular species in aquarium trade industry. Complete life-cycle culture of peppermint shrimp has been achieved in the laboratory, using newly hatched *Artemia* nauplii as the only food (unpublished data). However, there are still some obstacles in commercial production of the species. For example, there are variations in larval duration (ranging from 90 to over 100 days); sometimes embryos are aborted prematurely; and some larvae from captive broodstock have difficulty separating from the old exoskeleton during molting (unpublished data). Improving broodstock diet may enhance reproductive performance, thereby increasing the commercial production potential of the species.

Frozen adult *Artemia* can be used as a supplement or replacement of maturation diet for *Penaeus semisulcatus* (Browdy et al. 1989), *P. stylirostris* (Bray et al. 1990), and *P. vannamei* (Naessens et al. 1997). It is possible to boost the *Artemia* with nutritional supplements, such as highly unsaturated fatty acids (HUFAS), which may stimulate reproductive performance in shrimp. Individuals of *Penaeus chinensis* (Xu et al. 1992, 1994) and *P. indicus* (Cahu et al. 1995) fed with broodstock diets containing higher HUFAs produce better eggs with higher hatching rates. The tissue of clams, squid, or shrimp is rich in n-3 HUFA, arachidonic acid, cholesterol and other sterols, phospholipids, and essential amino acids, and appears to promote spawning success in penaeid shrimp (see Harrison, 1997 for a review).

The present study compares the effects of different types of frozen adult *Artemia* and hard clam *Mercenaria mercenaria* as broodstock diets on the reproductive performance of the peppermint shrimp.

MATERIALS AND METHODS

The study was conducted at Florida Institute of Technology, USA from May 1999 to May 2000. Farm-raised adult shrimp used in the experiment were purchased from Oceans Reefs & Aquariums, Inc. at Fort Pierce, Florida and maintained in a recirculating seawater system under 14 h light followed by 10 h dark. Water temperature was controlled at 27–29°C and salinity at 31–33 ppt. The shrimp were fed in excess once a day with one of the five test broodstock diets: four types of frozen adult *Artemia*: regular and enriched with (HUFA, phospholipids, steroids, carotenoids and vitamins) from two sources (Canada and San Francisco Bay); and frozen hard clam (*Mercenaria mercenaria*). Thirty-five shrimp of similar total length (TL, from the end of telson to the tip of rostrum) (Table 1) seven for each treatment, were used.

The shrimp were fed with the test diet for at least one month prior to collecting the following parameters: TL; wet body weight (WBW); fecundity (number of eggs); egg diameter and dry weight; and larval survivorship from Zoea 1 (Z_1) to Zoea 2 (Z_2). Two consecutive spawns from each experimental shrimp were used. Thirty newly hatched larvae (Z_1) were selected from the first spawn and TL of each larva was measured under a dissecting microscope with ocular. Each larva was then placed in a 270-ml transparent plastic cup with 220-ml seawater and fed with newly hatched *Artemia* nauplii. The number of larvae that survived to Z2 (30–36 hrs. later) was counted and survivorship was calculated.

At about 24 h after the second spawning, the entire egg mass was removed gently from the shrimp using small forceps and number of eggs were counted. Diameters of 30 eggs were measured under a microscope with an ocular micrometer. Egg volume was calculated using the formulae $V = 1/6(\pi d^3)$ for spherical eggs (d is the egg diameter) and $V = 1/6(\pi d_1 \times d_2^2)$ for prolate spheroids (d_1 is the least diameter and d_2 is the greatest diameter). One hundred eggs were separated from the rest of the eggs and all were dried at 70°C for 48 h. The total weight of the 100 eggs was measured to the nearest 0.01 mg using a digital balance and mean dry weight per egg was calculated. The spawned shrimp were dried on blotting paper, TL (to the nearest 0.1 mm), and WBW (to the nearest 0.1 mg) were measured.

Five different-sized shrimp (from 2.81 to 4.50 cm in TL) were used to compare the fecundity and egg volume from consecutive spawns. For each shrimp, fecundity and diameter of 30 eggs were measured from each of the two spawns.

One-way ANOVA was used to test the effect of different foods on average (of seven replicate shrimp) fecundity, relative fecundity (fecundity/g WBW), egg volume, dry egg weight, egg density (egg dry weight/egg volume), larval total length and survivorship from

Survivorship from Z_1 to Z_2 (%)	75.5 ± 10.2	87.6 ± 15.9	88.1 ± 9.2	71.9 ± 13.7	86.7 ± 4.7	*

* Significantly different ($P < 0.05$).

** Highly significantly different ($P < 0.01$).

ns, Not significantly different ($P > 0.05$).

Z_1 to Z_2, respectively, among the treatments. If the ANOVA result was significant, Fisher LSD method was employed to test for differences among the means. A two-tailed Student's *t*-test was used to compare the average fecundity and egg volume between the two consecutive spawns.

RESULTS

There was no significant difference in female total length among the five treatments (Table 1). Of the seven reproductive parameters measured, only egg volume and survivorship from Z_1 to Z_2 show significant differences among the treatments (Table 1). Egg volume from the regular San Francisco brand *Artemia* is significantly ($P < 0.01$) larger than those of the other treatments that do not significantly different from one another. The survivorship from Z_1 to Z_2 is significantly higher in the Canada enriched, San Francisco regular, and hard clam treatments than in the San Francisco enriched and Canada regular treatments (Table 1). There is no significant difference in fecundity ($P = 0.89$) between the first (mean ± s.d. = 953 ± 614) and the second (mean ± s.d. = 898 ± 464) spawns. Similarly, the difference in average egg volume between the first (mean ± s.d. = 0.0593 ± 0.0074 mm^3) and second (mean ± s.d. = 0.0533 ± 0.0074 mm^3) spawns is not statistically significant ($P = 0.23$).

DISCUSSION

Peppermint shrimp, also called red cleaning shrimp, may feed on parasites of fish in its natural environment, like many of its sibling species in the genus (Limbaugh et al. 1961, Debelius 1984, Jonasson 1987). Therefore, its natural diet may be narrow (although little is known on the relative importance and composition of parasites in the shrimp's natural diet). We found no significant difference in five of the seven reproductive performance parameters measured among the five-broodstock diets tested. There is no clear pattern in the two parameters (egg volume and survivorship from Z_1 to Z_2) showing consistent differences among the treatments. Larger eggs in the San Francisco regular treatment may be the result of larger (though not statistically significant) total length of the females, as egg volume correlates positively with maternal size in *Lysmata wurdemanni* (Lin and Zhang, unpublished data). In a sibling species, *L. debelius*, larval production is higher for those fed with live *Artemia* nauplii and those with enriched (with HUFAS, vitamins and others) frozen *Artemia* nauplii than those fed with regular frozen *Artemia* nauplii, which in turn is significantly and substantially (about 100%) higher than those fed with natural diets (mixture of fresh mussel and polychaete) (F. Simoes, pers. comm., 1998). However, in the same study on another sibling species, *L. amboinensis*, enriched frozen *Artemia* nauplii and natural diet resulted in the same level of larval production (F. Simoes, pers. comm. 1998). Browdy et al. (1989) demonstrated that using frozen adult *Artemia* as a dietary supplement can enhance reproductive performance of *Penaeus semisulcatus*. The reproductive activity was not consistent, however, and this may be due to possible variability in the nutritional quality of the different batches of *Artemia* used. The enrichment of *Artemia* is supposed to increase nutritional quality and reduce variability among *Artemia* batches. Naessens et al. (1997) showed that frozen *Artemia* may be useful as a supplement or replacement for polychaetes as maturation diet for *Penaeus vannamei*. However, brine shrimp biomass enriched with HUFAS did not perform better than the regular *Artemia* in their experiments. The authors caution the interpretation of the results and suggest that more research is needed to compare enriched and regular brine shrimp biomass and identify potentially active ingredients and their optimal doses.

ACKNOWLEGMENTS

We thank Feng Cen for her assistance in the laboratory. Florida Sea Grant (Grant #NA76RG-0120) and Maritech, Inc. provided financial support for the project.

THE TEXAS LIVE BAIT SHRIMP MARKET

RYAN GANDY,[1] TZACHI M. SAMOCHA,[1] EDWARD R. JONES,[2] AND DAVID A. MCKEE[2]

[1]Texas Agricultural Experiment Station, Shrimp Mariculture Research Facility, 4301 Waldron Rd. Corpus Christi, Texas 78418; [2]Texas A&M University–Corpus Christi, 6300 Ocean Drive, Corpus Christi, Texas 78412

ABSTRACT Decreases in wild catches coupled with increased regulations have attracted interest in the production of farm-raised live bait shrimp. Recent refinements in penaeid culture techniques suggest that the production of live bait is a potentially profitable endeavor. In this study, live bait shrimp dealers in Texas were surveyed by mail. The return rate was 8%. Returned surveys were found to be from 33 businesses from various locations over the entire Texas Coast. The information collected provides a small database that can be used to provide a broad and general view of the Texas market demand for farm-raised live bait shrimp. Texas market dynamics were characterized in terms of regional demands and seasonal fluctuations. Most live bait retail suppliers in Texas have been operating for 6–20 years, and during any given year they are able to meet the market demands for two only months. Most retailers expressed acceptance of a farm-raised product if it was of good quality and consistently supplied.

KEY WORDS: Texas, Gulf of Mexico, live bait shrimp, *Farfantepenaeus aztecus*, *F. duorarum*, *Litopenaeus setiferus*, survey

Historically, the supply of live bait shrimp for the eastern Atlantic and Gulf of Mexico coasts has relied on the harvest of wild *Farfantepenaeus aztecus* (Atlantic brown shrimp), *F. duorarum* (Atlantic pink shrimp), and *Litopenaeus setiferus* (Atlantic white shrimp). The overharvest of this natural resource forced the National Marine Fisheries Service to take action to maintain a sustainable yield of wild-caught shrimp (Warren 1980, McKee 1986, Southern Fisheries Science Center [SFSC] 1992, Nance 1993). The status of the Gulf of Mexico shrimp fishery for *F. aztecus*, *F. duorarum*, and *L. setiferus* was declared overexploited by the National Marine Fisheries Service in 1990 (SFSC 1992). The catch fishery is currently seen as overcapitalized, with more effort expended per unit catch than is economically feasible (SFSC 1992). The increasing overexploitation of the wild shrimp fishery has caused the bait shrimp fleet on the Texas coast to redirect its catch emphasis from the historically abundant white shrimp, *L. setiferus*, to the less abundant brown shrimp, *F. aztecus* (Texas Parks and Wildlife Department 1995). The Texas Parks and Wildlife Department's shrimp management proclamation recognizes that the continuing increase in the harvest of small shrimp (>67 count/lb) is ecologically unsustainable and that it will cause shrimp stocks to collapse (Texas Parks and Wildlife Department 1993). The decline in wild harvests along the Texas Coast was observed, as early as 1986, to have an effect on retail markets (McKee 1986). McKee et al. (1989) observed that the retail demand for live bait shrimp in Texas waters was greater than what the bait shrimp fleet was able to supply.

The status of the fishery prompted the establishment of a Gulf of Mexico management plan and prompted the South Atlantic Management Council in 1981 to regulate the fishery along the Gulf of Mexico and eastern coast of the United States. Regulations at the state level have also been forthcoming. In 1995, the state of Texas signed into law HB750, which imposed new regulations on bait shrimpers. This bill was designed to provide long-term conservation of shrimp stocks and to create economic stability in the bait shrimp fishery (Texas Parks and Wildlife 1995). For example, the bill limits the number of future bay bait shrimping licenses, which will eventually lead to a reduction in the bait fishing fleet.

Due to the great demand and high dollar value of live bait shrimp, the production of farm-raised live bait shrimp has attracted much attention in the past few years. Recent studies have reported on the profitability of producing cultured live bait shrimp using modern farming techniques (McKee 1986). Limited data were available concerning the economic viability of a live bait shrimp farm (Parker & Holcomb 1973, Quick & Morris 1976, Rossberg & Strawn 1980). The initial research concluded that farming live bait shrimp was unprofitable (McKee et al. 1989). However, recent studies suggest that the production of live bait shrimp is a potentially profitable endeavor (Sandifer et al. 1993, Burkott 1994, Samocha et al. 1998). These studies have focused on the manipulation of stocking density, the development of new culture techniques, and pond management to improve the profitability of live bait shrimp production.

Past studies concerning Texas' demand for live bait shrimp relied on National Marine Fisheries Service landing reports and personal interviews in Texas (McKee 1986, Burkott 1994). These studies provided only a partial estimation of consumption, production volume, and a general pricing structure of this market because data were collected mainly from local markets. Assessment of the true potential of a live bait shrimp farming requires an understanding of production and infrastructure costs, market demand, and market price data for the major regions of this market.

The objectives of the current study were (1) to collect information concerning the live bait shrimp business type and market environment in Texas, (2) to analyze the supply and demand relationships of live bait shrimp within this region; and (3) to assess the acceptability of farm-raised live bait shrimp by retailers.

A mail-out survey was used to collect data on the regional live bait shrimp market demand and supply. In general, the data characterize seasonal fluctuations in the supply and demand of bait shrimp. In addition, this survey provides an overall view of the variation in the Texas wholesale pricing structures, quantity demand, mortality rates of wild-caught live bait shrimp, average quantity demand of each retail outlet, and acceptance of farm-raised bait shrimp by retailers. These data also provide an understanding of regional quantity demand, species usage, and the size of live bait shrimp preferred by this market.

MATERIALS AND METHODS

The research was conducted at the Texas Agricultural Experiment Station Shrimp Mariculture Research Facility in Corpus

Christi, Texas. Mailer information of live bait dealers was obtained from the Texas Parks and Wildlife Department. Survey forms were mailed to the 412 licensed live bait dealers in Texas. The survey contained 31 multiple-choice questions and two short-answer questions. Questions were presented in an easy-to-read format. The surveys were mailed between July 25, 1996 and August 5, 1996 with a self-addressed stamped return envelope to improve the rate of return.

RESULTS AND DISCUSSION

Of the 412 licensed Texas bait dealers, 33 returned the survey (8% return rate). The low return rate of this survey suggests some inherent bias due to the use of a small data set. The return data, when grouped by physical location along the Texas coast, shows that the returned surveys were not from one specific area. These surveys were in fact from 33 businesses from various locations over the entire Texas Coast. From this data set, which is limited in volume but broad in scope, it is possible to understand the Texas market from a general perspective.

The Texas live bait shrimp retail market is comprised of retailers who have been operating in this market for 6–20 y (Fig. 1). Texas retailers indicated an increase in live bait shrimp demand over the past 5 y without an increase in supply. The inability of the bait shrimpers to supply the Texas market, observed in the early years by McKee (1986), appears to continue today. Texas retailers indicated that a general lack of supply is expected nearly all year round. Texas retailers expect a semi-consistent supply of live bait shrimp in May, June, and October; however, this supply is not reliable (Fig. 2), although the highest demand for live bait shrimp by fishermen lasts from April to October (Fig. 2). The primary limiting factor in meeting the demand is the bait shrimping laws that limit catches to 200 lb/vessel/day (TPWD 1995).

The sales of live bait shrimp accounted for more than 50% of the sales for 29% of the live bait dealers. Another 29% of the dealers reported live bait shrimp sales that accounted for 25–49% of their total sales (Fig. 3). Live bait shrimp is the key to success for all bait and tackle stores. Lack of live bait also effects the sales of other merchandise in a bait and tackle store.

In Texas, the holding capacities are limited to 22–45 kg (50–100 lb.) of live shrimp per retailer. The retailers are restocked daily during the high-demand periods and daily to weekly during low-demand periods. Under the high demand for bait shrimp in this market, supply becomes an important factor. Ninety-four percent of the retailers surveyed responded that three local suppliers supply them; only a small portion of the Texas supply is imported from Florida.

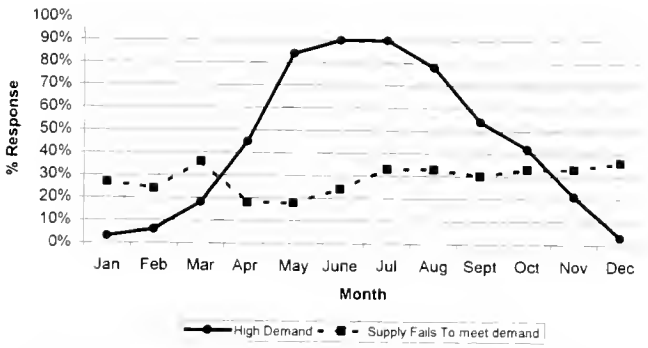

Figure 2. Consumer demand vs. availability for Texas live bait shrimp market.

The controlling factors involved in the selection of a supplier by Texas retailers are availability and consistency. The ability of a farm-raised product to meet these criteria illustrates its advantage over the wild-caught live bait shrimp. When asked if they would purchase a farm-raised product, 74% of the retailers replied positively, provided the supply is consistent and of good quality (e.g., hardy animals with minimal signs of broken appendages and lesions).

This survey showed that 36% of the live bait shrimp dealers in Texas listed *F. aztecus* as their species of choice, 24% preferred *F. duorarum*, 21% had no preference, and 15% preferred *L. setiferus*. The data further corroborates the earlier study by McKee (1986), which suggested that sport fishermen prefer brown shrimp due to its greater availability and high tolerance to stress.

The current study further suggests that the majority of the live bait shrimp are purchased by the gallon (3.785 l) with a size preference of 60–70 count/lb (132–154/kg) or individual shrimp weight between 6.5 and 7.6 g. The average price for this size of shrimp was $21.23/g. Inglis and Chin (1966) reported a retailer preference for 80-count/lb shrimp (5.76 g per shrimp). On the other hand, Quick and Morris (1976) suggested a preference for 200-count shrimp (2.27 g per shrimp). Our data corroborates the wholesale and retail pricing trends suggested by earlier studies.

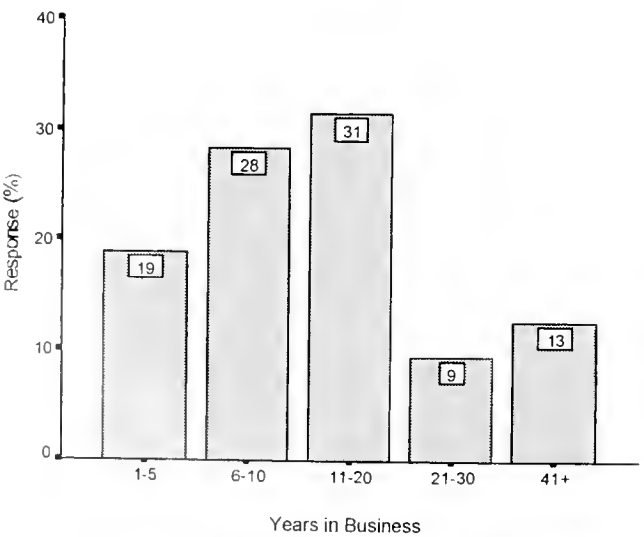

Figure 1. Texas live bait shrimp retail business age.

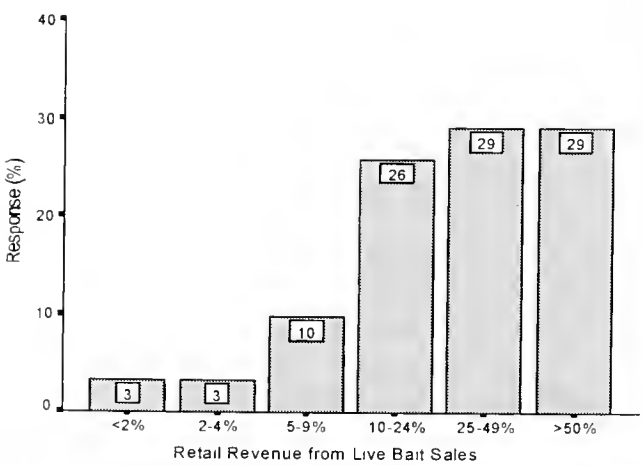

Figure 3. Percent revenue expected by retailers from sales of live bait shrimp.

The wholesale price for bait shrimp has been documented to fluctuate according to supply, whereas the retail price remains constant within a region (McKee 1986).

Prior studies have reported an accepted mortality of 10–20% for live bait shrimp after delivery (McKee 1986). This survey found the expected mortality to be higher. Forty percent of the retailers expected the standard 10–24% mortality per shipment, whereas 20% expected 25–49% mortality (Fig. 4). This great loss of stock translates directly into lower revenues. Although lack of stock has an impact on sales, the weather was cited as the primary controlling factor that negatively impacts retail sales.

This study has concluded that, in general, the Texas market for live bait shrimp is largely undersupplied during the highest demand periods of the year. Whether this is due to a declining resource or due to tighter catch restrictions is a point of contention. However, the fact remains that this market has a considerable lack of supply. Live bait shrimp sales account for a majority of retailers' yearly revenue. This is due to the ability of live bait shrimp to drive the sales of other items in bait stores (e.g., equipment and food) if it is available. Thus, it is easy to see that the market is not realizing its full potential without a consistently available and reliable product. The acceptance of a farm-raised live bait shrimp, with its flexible product characteristics, would allow it to meet the major demands of the Texas market.

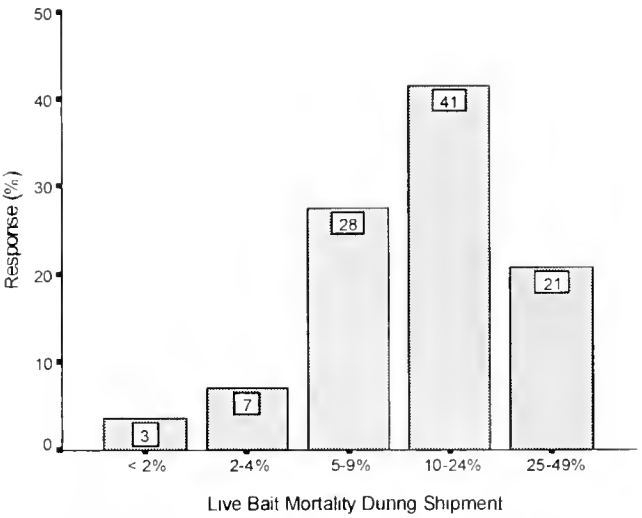

Figure 4. Expected live bait shrimp mortality during shipment.

THE REPRODUCTIVE CYCLE OF GOLDEN KING CRAB *LITHODES AEQUISPINUS* (ANOMURA: LITHODIDAE)

A. J. PAUL* AND J. M. PAUL

University of Alaska Institute of Marine Science, Seward Marine Center Laboratory, P.O. Box 730, Seward, Alaska 99664

ABSTRACT Female golden king crabs *Lithodes aequispinus* were held in captivity to determine the duration of their reproductive cycle. The time between the first and last egg hatching was 34 days (SD = 16, n = 147) on average. Females molted about 192 days (SD = 72, n = 111) after the last egg hatched. Eggs were extruded 2 days (SD = 2, n = 61) after molting. Egg clutches were incubated for an average of 362 days (SD = 78, n = 59). The average amount of time that passed between the production of successive egg clutches was 590 days, or 3,570- degree days of water temperature.

KEY WORDS: *Lithodes aequispinus*, reproduction, king crab

INTRODUCTION

The golden king crab, *Lithodes aequispinus* Benedict, supports an important fishery in Alaska. This North Pacific species typically lives in deep water, on untrawlable bottoms. Because of their remote deep habitat, and the fact that only males are retained by the fishery, the reproductive cycle of females had not been described in detail prior to this study. Female golden king crabs carry up to 27,000 large eggs (Jewett et al. 1985) that can hatch in any month of the year (Adams and Paul 1999). Female golden king crabs are found in all reproductive and molting stages throughout the year (Paul and Paul 2000a), so the duration between clutches was not apparent from gross examination of the egg mass. This laboratory study examined the reproductive cycle of the golden king crab to identify how long it took females to go from the extrusion of one egg clutch to another. This study was accompanied by parallel studies on growth of both sexes (Paul and Paul 2000a) and sizes at maturity of males (Paul and Paul 2000b).

MATERIALS AND METHODS

Crabs needed for the study were captured with pots fished at 108 to 152 m depths on the western side of Prince William Sound, Alaska. After capture the specimens were transported to the Seward Marine Center Laboratory by floatplane. No mortalities occurred during the transport process. Collections of multiparous females were made November 11–14,1996; May 1, 1997 and October 10–20, 1998. Observation of captives continued until October 1, 2000.

The carapace length (CL) of all crabs was measured to the nearest millimeter for the growth study (Paul and Paul 2000a), and they were tagged with a numbered plastic disk attached to the leg with a plastic cable tie. All females in this study had egg clutches when captured and they had carapace lengths ranging from 104 to 150 mm ($\bar{x}$ = 132, SD = 7 mm). Each female was held in a separate 800 to 1000 L tank. The seawater in the tanks was exchanged ≥100% per hour to maintain the ambient temperature of incoming water from 75 m depth in Resurrection Bay. The water temperature in the tanks was measured daily. The duration of each of the 4 reproductive phases was described as both, number of days and degree-days of water temperature. The degree-day intermolt period is considered the sum of the average daily temperature during the intermolt period. Thus for example, if a stage interval was 30 days and the temperature every day was 6°C, the event spanned 180-degree days (30 × 6). The degree-day duration data was calculated because the reproductive phases were nonsynchronous with some females extruding new clutches in the warm part of the year and others during the cold season. Temperature in the tanks followed the fjord's seasonal cycles ranging from 3.7 to 9.7°C (Fig. 1). Crabs were fed every other day to excess with a repeating cycle of the following foods: whole Pacific herring *Clupea pallasi* Valenciennes 1847, fillet of coho salmon *Oncorhynchus kisutch* (Walbaum 1792), giant Pacific Octopus *Octopus dofleini* (Wulker 1910), whole squid (species unknown), and whole Alaska northern shrimp *Pandalus eous* Makarov 1995.

STAGE 1 (n = 147) was the length of time between the hatching of the first and last egg. STAGE 2 (n = 111) started after the last egg hatched and it ended when a female molted. STAGE 3 (n = 61) was the length of time between the day a female molted and the day she extruded a new egg clutch. The duration of clutch incubation (STAGE 4) was the length of time between the extrusion of a new egg clutch and the hatching of all those eggs (n = 59). Thus, STAGE 1 and 4 overlap. The duration of the different phases of the full reproductive cycle was not quantified for every female since captives had different collection dates.

Tanks were examined daily for the presence of larvae and when the first larvae were seen, females were examined every day until all eggs had hatched. This procedure was used to determine the duration of the larval hatching phase, STAGE 1. Thereafter, females were isolated from males until they molted. Females must molt prior to mating. These observations estimated the time between egg hatching and molting, STAGE 2.

After a female molted a selected hardshell male ≥114 mm CL was put into the tank with her. Males of this size are capable of fertilizing females (Paul and Paul 2000b). The time between the molt and the occurrence of the new egg clutch was termed STAGE 3. After ovulation, females were isolated and held until zygotes developed to the 64-cell stage. Groups of at least 100 eggs from each pleopod were then randomly selected and examined under a microscope for cell division to determine percent viability. Females were held from ovulation until hatching to determine the incubation period, STAGE 4.

RESULTS

STAGE 1, the period between the first and last larvae hatching, averaged 34 days (SD = 16, n = 147, range 8–85) or 202 degree days (SD = 88, range 19–474). On average 192 days (SD = 72,

*Corresponding author. E-mail: ffajp@uaf.edu

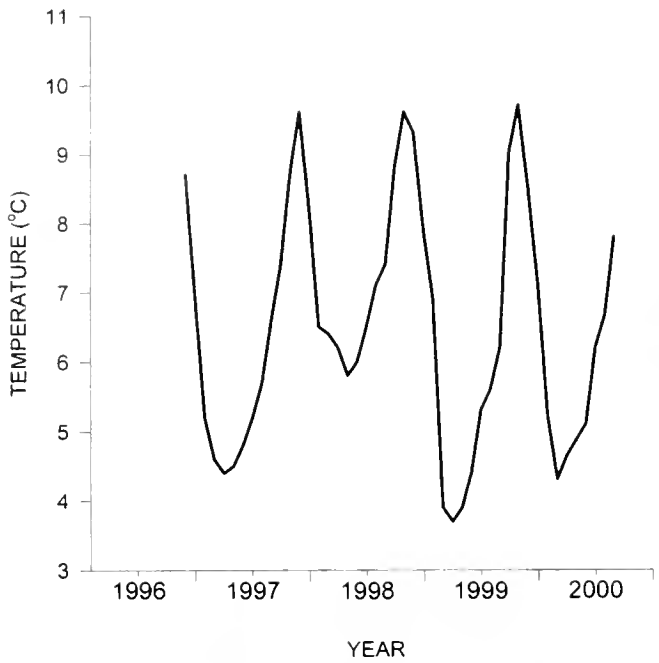

Figure 1. Laboratory seawater water temperatures during the study.

n = 111, range 5–464) or 1,084 degree days (SD = 428, range 36–2,762) passed after the last larvae hatched until the females molted which completed STAGE 2. During STAGE 3 females typically extruded new eggs 2 days (SD = 2, n = 61, range 1–12) or 15 degree days (SD = 12, range 4–85) after molting. All clutches resulting from these laboratory matings had ≥80 of their eggs initiating division. STAGE 4, egg clutch brooding, lasted an average of 362 days (SD = 78, n = 59, range 40–569) or 2,269 degree days (SD = 570, range 114–2,754). The total time passing between egg clutches averaged 590 days or 3,570 degree days. The best fitting regressions relating the CL (mm) of all females that completed STAGES 1–4 and their reproductive cycle duration (degree days) showed no apparent relationship between these variables ($r^2 \leq 0.12$).

DISCUSSION

In early studies the time of spawning of golden king crab was described both as seasonal asynchronous and synchronous (Sloan 1985). Some of this reported variability may have been caused by an imperfect understanding of the reproductive cycle. During STAGE 2 ($\bar{x}$ = 192 days) females carry decaying empty egg capsules on their setae (Sloan 1985) and this condition made it difficult for fishery observers to classify the reproductive status of females.

For Prince William Sound golden king crab, molting and hatching events can occur in any month in captive females (Paul & Paul 1999, Paul & Paul 2000a). Thus, their reproductive cycle is markedly different from the genus *Paralithodes*. In red king crab *Paralithodes camtschaticus* (Tilesius) the female reproductive cycle is synchronous, lasting about one year (Paul & Paul 1990, Paul & Paul 1997). In blue king crab (*Paralithodes platypus* Brandt) primiparous females may produce egg clutches annually and every two years for larger multiparous females. Like red king crabs, the eggs of primiparous and multiparous blue king crab hatch during the spring plankton bloom (Jensen & Armstrong 1989). Red king crabs hatch their eggs in spring so the larvae can feed on the plankton bloom (Paul et al. 1990), then all ripe females molt and breed soon after hatching is done. With golden king crab, hatching does not need to occur exclusively during the spring plankton bloom because their lecithotropic larvae do not feed and they can tolerate both summer and winter temperatures (Shirley & Zhou 1997, Adams & Paul 1999, Paul & Paul 1999). One striking difference between the reproductive cycle of golden and red king crabs is the amount of time between egg hatching and the female molt. In red king crabs captive females usually molt within two weeks of egg hatching (authors' unpublished observations) vs. about six months for golden females. Currently it is not known why these differences exist. Golden king crab females may need more time to produce the large yolk rich eggs that allow their larvae to forgo feeding. However, that idea is speculation at this time.

Female Prince William Sound golden king crab first mature around 120 mm CL and typically grow to about 150 mm CL in 5 molts (Paul & Paul 2000a). If they produced an egg clutch every molt, and their reproductive cycles lasted 590 days, females would have to survive at least eight years to produce 5 clutches.

The sea water for holding the crabs came from a 75 m depth where temperatures during August to December are 1 to 4°C warmer than at approximately 150 m where the specimens were captured, versus 1 to 2°C cooler from January to April (Xiong & Royer 1984). Generally warmer conditions decrease intermolt duration in crustaceans unless there is thermally induced stress and cooler ones lengthen it. Only *in situ* studies, or laboratory studies that mimic site specific temperatures, can determine if our degree day estimates for the reproductive cycle duration are appropriate for female golden king crab living in different thermal environments.

INTERMOLT DURATIONS OF CAPTIVE JUVENILE AND ADOLESCENT MALE TANNER CRABS *CHIONOECETES BAIRDI*

A. J. PAUL* AND J. M. PAUL

University of Alaska, Institute of Marine Science, Seward Marine Center Laboratory, P.O. Box 730, Seward, Alaska 99664

ABSTRACT This project examined the effect of temperature on intermolt durations of juvenile and adolescent male *Chionoecetes bairdi* Rathbun with carapace widths (CW) of 11 to 105 mm. Juveniles were identified by the absence of spermatophores and adolescents by their presence. The relationship between male maximum CW and intermolt duration exhibited a linear relationship for juveniles described by the equation: Intermolt period (degree-days) = 7.9 (CW mm) + 272; $r^2 = 0.53$. As males began to produce spermatophores at about 55 mm CW intermolt durations increased and the analogous equation was Intermolt period (degree-days) = 7.6 (CW mm) + 1,215; $r^2 = 0.14$. A 55 mm CW spermatophore bearing male took about 2.5 times longer to molt than a similar sized juvenile.

KEY WORDS: *Chionoecetes*, molting, temperature, tanner crab

INTRODUCTION

In the northern Gulf of Alaska and the southeastern Bering Sea the Tanner crab, *Chionoecetes bairdi*, is a ubiquitous benthic invertebrate that is harvested commercially. The change in carapace size following molting has been described for Gulf of Alaska *C. bairdi* (Donaldson et al. 1981, Paul & Paul 1996) but the intermolt duration has not. Information on intermolt duration is critical to understanding recruitment to the population because there is no accepted method to age Tanner crabs (Rosenkranz et al. 1998). Crustacean growth rates are controlled by a number of factors with temperature being one of the most obvious (Fisher 1999). Benthic temperatures in the Gulf of Alaska experience long term warming and cooling cycles of about 18 to 20 years (Royer 1989). In addition to seasonal changes in temperature El Niño events, like that of 1998 (Fig. 1), are additional sources of thermal perturbations. The inter-annual differences in the mean monthly bottom temperature where the specimens for this study were captured were on order of 2 to 3°C (Fig. 1). Currently there is no information on the effect warm and cold periods have on the duration of molting rates of *C. bairdi*. It is logical to assume that thermal conditions will be a major factor regulating the length of the intermolt period. The objective of this study was to determine the intermolt period of juvenile and adolescent male Tanner crabs in degree-days. This study was funded to improve our understanding of the growth process and the relative age of males recruiting to adulthood. In earlier observations of size of maturity and growth in male Tanner crabs (Adams & Paul, 1983; Paul & Paul, 1996) it appeared that immature males took less time to molt than mature males of similar sizes but this was not quantifiable with the methods used. We speculated that the molting schedules of mature and immature males would be markedly dissimilar, so we ascertained the maturity status of test specimens to examine this theory.

MATERIALS AND METHODS

Male Tanner crabs were collected at the head of Resurrection Bay near Seward Alaska at 35 to 80 m depth using a 2 m otter trawl with 6 mm cod end mesh at a variety of times during the years 1996 to 2000. There were 67 males with carapace widths (CW) 9 to 82 mm that were returned to the nearby laboratory for the study. The seawater for the Seward Laboratory comes from 75-m depth in a fjord and its temperature during the study was 3 to 10°C (Fig. 1). The temperature of the incoming water changes with season with marked inter-annual variations in monthly values (Fig. 1). Each day the seawater temperature in the tanks was recorded. Salinity ranged from 31 to 33 ppt. All test animals were held in separate numbered tanks to prevent cannibalism. Males ≤45 mm were held in individual 20-L tanks. Males ≥46 mm were held in 100-L tanks and the water exchange rate in all tanks was 100% per h.

Captives were fed to excess every Monday (whole northern shrimp *Pandalus eous* Makarov 1995), Wednesday (live intertidal mussel *Mytilus trossulus* Gould 1850) and Friday (Coho salmon fillet *Oncorhynchus kisutch* Walbaum 1792). Whenever a male molted for the first time in captivity the date of molting was recorded. After two weeks had passed, and the carapace had hardened, its maximum CW was measured to the nearest 0.1 mm. The new post molt CW of the smallest captive was 11 mm and the largest 105 mm CW. A three millimeter coded plastic disk was glued to the carapace of test specimens. The date of each crab's second molt was recorded to calculate the intermolt duration. The new CW was measured two weeks later and the vas deferens was removed to determine if spermatophores were present in wet mounts using 100× magnification.

The intermolt duration was described in degree-days. Degree-days were calculated by summing the daily seawater temperatures that occurred during the intermolt period. For example if an event took ten days, and each day the temperature measurement was 10°C, then the process would have taken 100 degree days.

RESULTS

The relationship between male CW and intermolt duration exhibited a linear relationship for juveniles that was described by the equation: Intermolt period (degree-days) = 7.9 (CW mm) + 272; $r^2 = 0.53$, $P < 0.0001$, $n = 53$ (Fig. 2A). The relationship between CW (mm) and intermolt duration for males producing spermatophores was described by the equation: Intermolt period (degree-days) = 7.6 (CW mm) + 1,215; $r^2 = 0.14$, $P = 0.1832$, $n = 14$ (Fig. 2B). The intermolt duration of mature males was less dependent on temperature than that of juveniles. The intermolt durations of males that were producing spermatophores (Fig. 2B, C) were longer than would be expected if the linear models of intermolt

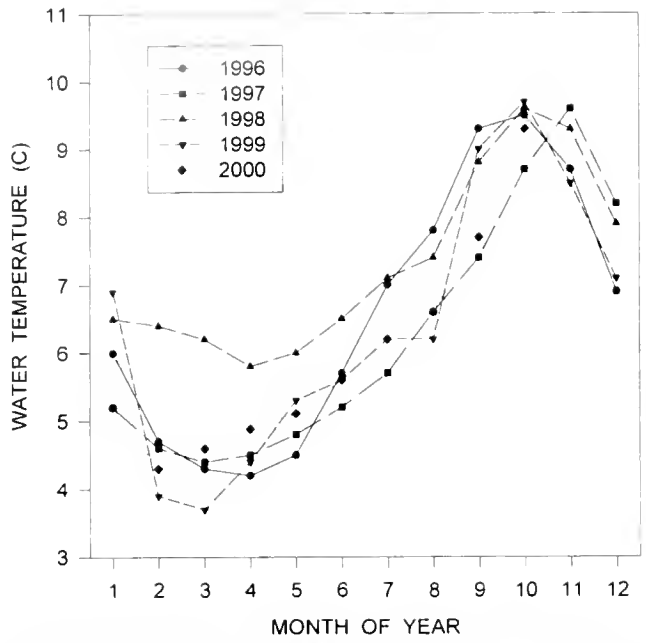

Figure 1. Seawater temperatures at 75 m depth in Resurrection Bay, near Seward Alaska between 1996 and 2000.

duration for juvenile individuals (Fig. 2A) and adolescents (Fig. 2B) coincided (Fig. 2C). For example, the largest male without spermatophores was 56 mm CW and it had an intermolt duration of 672 degree-days (Fig. 2C). The smallest male with spermatophores was 55 mm CW and 1,692 degree-days passed before it molted (Fig. 2C).

Based on the equation describing the intermolt duration (Fig. 2A), and using the growth per molt equation of: New CW = Initial CW (1.14) + 4.1; $r^2 = 0.97$ (Paul and Paul 1996) we estimate that a recently metamorphosed Tanner crab of 3 mm CW would require approximately 3,639 degree days to reach 63 mm CW (Table 1), a size when >50% of Gulf of Alaska males have spermatophores (Paul 1992). A spermatophore bearing male 63 mm CW would require about 7,414 degree-days to grow to 107 mm CW (Table 2), a size close to that of the largest individual that molted in this study. The largest male in the study was 105 mm CW and it molted after 2,001degree-days. The smallest male in the study was 11 mm CW and it molted after 477 degree-days.

DISCUSSION

It is generally accepted that the amount of time that passes between molts increases with crab carapace size, and this proved to be true for *C. bairdi*. We are not sure why small spermatophore bearing males had longer intermolt periods than similar sized im-

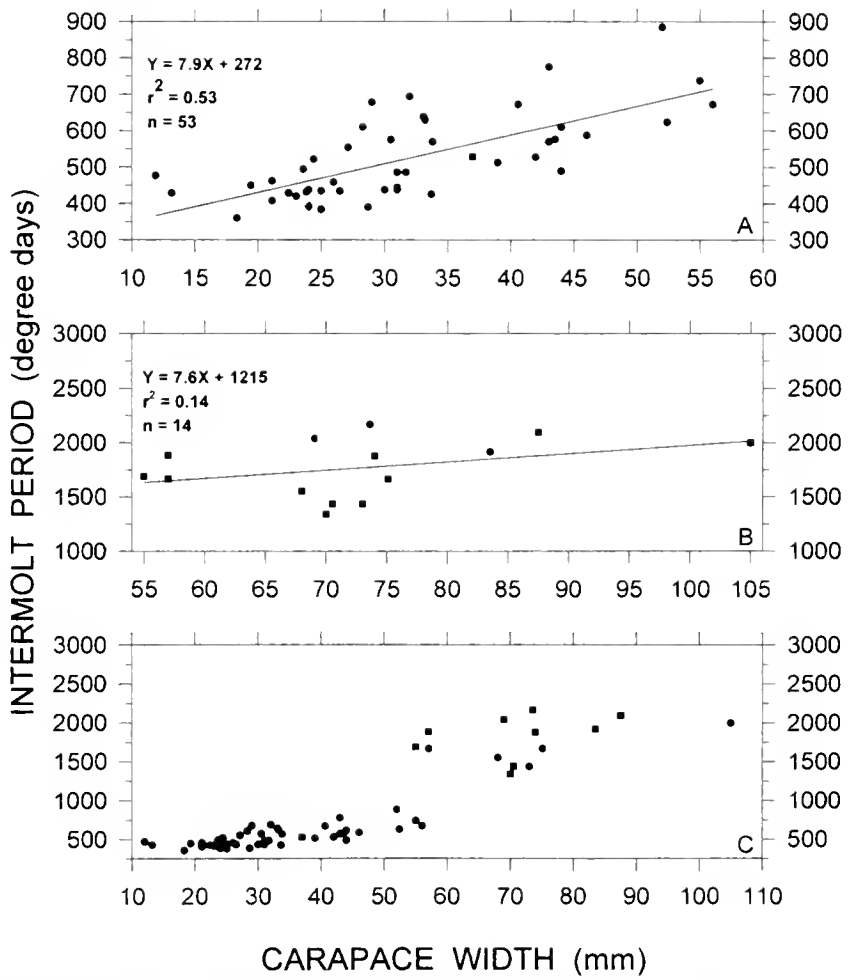

Figure 2. Intermolt durations in degrees days for juvenile male *Chionocetes bairdi* that did not have spermatophores in their vas deferens (Panel A, ●), spermatophore bearing males (Panel B, ■), and comparisons of both types (Panel C).

mature males. Perhaps spermatophore production is only one element of a complex maturation process with morphological, biochemical and physiological changes that involves longer intermolt periods. Currently, no other information on the intermolt durations of juvenile Tanner crabs, or closely related high latitude species, is available to compare to our results. The smallest Tanner crab we have seen in trawl samples is 3 mm CW. Our intermolt duration projections (Tables 1, 2) imply that captive Tanner crabs would grow from 3 to 107 mm CW in 11,053 degree-days. In our laboratory the average annual seawater temperature is about 6° C, and a male held at 6°C would require approximately 1842 days or 5 years to grow from 3 to 107 mm CW. However, we do not know if laboratory conditions, for example tank size, modified molting schedules. In the laboratory a surplus of food was present while in nature food availability may limit growth rates. It is also possible that the laboratory diet was nutritionally incomplete. This study needs replication with *in situ* tagging studies to determine if our laboratory molting schedules are applicable to natural conditions.

These observations on intermolt durations demonstrate that size and maturity status are important factors to consider when forecasting molting schedules in Tanner crabs <105 mm CW. Tanner crab males are not harvested until they are ≥140 mm CW and they can grow to ≈170 mm CW. Thus, molting rate studies need to be done with larger specimens than we used in this observation. Additional experimentation with large crabs would be especially important if there are maturation processes other than spermatophore production that influence molting schedules. Juvenile and adolescent males typically have relatively small claws while fully mature males have large claws (Stevens et al.1993). All the males in this study were small claw morphotypes using the criteria of Stevens et al. (1993), the ratio of chela height/CW <0.17, and most intermolt durations were one year or less. Males continue to molt after reaching maturity (Paul and Paul 1995) presumably because big large-claw males win competitions for mates, and compromised carapaces need replacement. The large claw characteristic develops when males reach 100 to 130 mm CW (Stevens et al. 1993). We studied the consequence of spermatophore presence on molting rates, but not the change to the large claw morphotype, or the attainment of near maximum CW. In another investigation Tanner crabs with CW ≥110 mm had to be held for over two years before they molted (Paul and Paul 1995). None of them were soft-shelled when they were captured, so their intermolt period was longer than two years. In one *in situ* study 47% of tagged male *C. bairdi* > 110 mm CW were recaptured after two years and another 7% after three years (Donaldson 1980). These observations (Donaldson 1980, Paul and Paul 1995) suggest that intermolt durations increase after males assume the large claw morphotype and approach maximum size. Further growth rate studies with males 105 to 170 mm CW are needed to describe the intermolt durations of these large individuals.

EFFECT OF ARTIFICIAL DIETS CONTAINING CAROTENOID-RICH MICROALGAE ON GONAD GROWTH AND COLOR IN THE SEA URCHIN *PSAMMECHINUS MILIARIS* (GMELIN)

GILLIAN McLAUGHLIN[1] AND MAEVE S. KELLY[2,*]

[1]*Department of Zoology, University of Aberdeen, Aberdeen, AB24 2TZ, Scotland, United Kingdom;*

[2]*Scottish Association for Marine Science, PO Box 3, Oban, Argyll PA34 4AD, Scotland, United Kingdom*

ABSTRACT Gonadal growth and color were examined in the echinoid *Psammechinus miliaris* when fed diets containing either micro- or macroalgal supplements. Urchins receiving diets containing the microalgae *Phaeodactylum tricornutum* and Tahitian *Isochrysis* sp. showed significantly greater gonad growth at the end of the 12-wk experimental period as compared to urchins fed the artificial diet with no added algae. An improvement in gonad color, compared to the control, was observed for both treatments receiving microalgae; whereas, those fed the macroalgae *Laminaria saccharina* diet showed no significant improvement in color. The *P. tricornutum* diet improved gonad color more rapidly than the other algal diets. These results show that cultured microalgae, incorporated into an artificial diet, have a positive effect on the gonad color of *P. miliaris*, with promising implications for commercial echinoculture.

KEY WORDS: sea urchin, *Psammechinus miliaris*, artificial diet, carotenoid pigments, gonad color, echinoculture

INTRODUCTION

The gonads of sea urchins (Echinodermata, Echinoidea) are a highly sought-after product in many parts of the world, particularly in the Far East and Mediterranean Europe (Hagen 1996). The global demand for sea urchins has risen sharply over the past two decades, and as a result, most commercial sea urchin fisheries are now considered to be fully or overexploited (Keesing and Hall 1998). Attention is, therefore, turning toward the development of a commercially viable echinoculture industry.

Artificial diets have been shown to enhance gonad growth effectively in several commercially important sea urchin species (de Jong-Westman et al. 1995, Lawrence et al. 1997, Barker et al. 1998, Robinson & Colbourne 1998, Fernandez & Pergent 1998). However, in addition to an acceptable quantity of gonad per individual, the marketplace also requires the gonad to be a bright orange color. Addressing the problem of variability in gonad color is, therefore, an important part of artificial diet design.

Carotenoid pigments, the source of red, orange, and yellow coloration in plants and animals are synthesized only by plants and micro-organisms. Animals can, however, alter these molecules by oxidation. The coloration of urchin gonads is a result of selective accumulation and chemical modification of carotenoid pigments obtained from their diet (Goodwin 1984). Griffiths & Perrot (1976) found the primary carotenoids in the ovaries of *Strongylocentrotus droebachiensis* were echinenone (79 – 85%), β-carotene, zeaxanthin, isocryptoxanthin, and small amounts of a fucoxanthin isomer. Echinenone was subsequently shown to be the primary carotenoid in the gonads of 11 species of urchin from Japanese waters (Tsushima & Matsuno 1990) and of the New Zealand echinoid *Evechinus chloroticus* (Goebel & Barker 1998).

Hallenstvet et al., (1978) described the total purified carotenoid content of whole *P. miliaris* as fucoxanthinol 68%, echinenone 10%, lutein 8%, β-β carotene 10% and β-ε carotene 5%, but did not report the relative amount of gonad tissue present or the color of the gonads of the urchins they analyzed. Griffiths and Perrot (1976) found that gut wall of S. *droebachiensis* contained 7–24 times the carotenoid content of the ovaries on a dry weight basis, but that there was little evidence to suggest that fucoxanthin, the main carotenoid of the gut wall, was used in the production of echinenone, the main pigment of the ovary. They presented evidence that echinenone was a conversion product of ingested β-β carotene (via isocryptoxanthin) and that this conversion occurred in the ovary and not in the gut wall. Tsushima et al. (1993) subsequently showed β-carotene to be the precursor for echinenone, via β-isocryptoxanthin, in *Pseudocentrotus depressus*. However, Goebel and Barker (1998) have shown that feeding processed carrot pulp or synthetic β-carotene supplements to *Evechinus chloroticus* produced no significant effect on the gonad color.

Gonad growth was shown to be significantly enhanced in *Psammechinus miliaris* when fed on commercially prepared salmon diets, either directly or in polycultured systems (Kelly et al. 1998b; Cook et al. 1998). Although the salmon feed contained the carotenoid astaxanthin, these urchins produced gonads of a duller orange than the bright and most desirable shades found occasionally in local wild populations of *P. miliaris*. Similarly, Havardsson and Imsland (1999) found no evidence to suggest *S. droebachiensis* could utilize such higher oxidation state pigments as astaxanthin as metabolic precursors for echinenone.

Wild *P. miliaris* are often found feeding on the macroalgae *Laminaria saccharina* (Kelly 2000) and a range of encrusting invertebrate species (Lawrence 1975). The addition of macroalgae as a source of carotenoids in urchin artificial diets may enhance gonad color; however, macroalgae typically exhibit seasonal biochemical variations (Black 1950) that could result in variability of the final product. However, microalgae that contain carotenoids can be cultured under controlled conditions and on a large scale using existing technology. The aim of this investigation, therefore, was to determine if incorporating carotenoid-rich microalgae into artificial diets for *P. miliaris* had a positive effect on gonad color and growth.

MATERIALS AND METHODS

Sea Urchin Collection and Maintenance

Psammechinus miliaris were collected by SCUBA from a depth of 5 m in Loch Creran, Scotland (56°32′20″N; 5°17′00″W).

*Corresponding author.

Twenty-two urchins (horizontal test diameter 20–30 mm), selected at random, were placed into each of 12 10:1 aquaria. Each aquarium had an independent supply of 250 μm filtered seawater at ambient temperature and salinity. The experiment was conducted over twelve weeks from May to August 1999, when the seawater temperature ranged from 9.9–15.3°C. The photoperiod was maintained at a constant 16-h light: 8-h dark cycle throughout the experiment.

The urchins were left to acclimatize to the aquarium conditions for a period of sixteen days before the start of the experiment, during which time they were starved to standardize their nutritional status (Vadas 1977). The urchins were then fed one of four diets at a constant rate of approximately 3% of their mean body weight per day. Any waste food and feces were removed every second day by carefully siphoning around the urchins.

Diet Preparation

The diets were allocated to aquaria using a randomized block design, with three replicates of each treatment. The diets were made from commercially available raw materials (Table 1) with either additional micro, macro, or no additional algae (as a control). Agar and gelatine were chosen as suitable binding agents (Caltagirone et al. 1992), and the food pellets retained a firm consistency in seawater when subjected to urchin grazing. The microalgae were obtained from the Culture Collection of Algae and Protozoa (CCAP), Dunstaffnage Marine Lab., Oban, UK. The species used were the diatom *Phaeodactylum tricornutum* Bohlin (CCAP 19/18) and the flagellate Tahitian *Isochrysis* sp. (Parke) (T-ISO, CCAP 927/14). The macroalgae *Laminaria saccharina* (L) Lamour was collected locally.

The microalgal strains were selected on the basis of their pigment profiles and their growth characteristics. The diatom *P. tricornutum*, belonging to the Bacillariophyceae, has as its major carotenoid pigments the xanthophylls fucoxanthin and diadinoxanthin and small amounts (<1% of total carotenoid content) of β-β carotene and cis-β-β carotene (Wright et al. 1991). T-ISO, a golden-brown flagellate (Prymnesiophyceae) similarly contains the carotenoids fucoxanthin, diadinoxanthin, and smaller amounts of β-β carotene (Brown et al. 1993). *L. saccharina* has fucoxanthin as its primary xanthophyll and violaxanthin as the second major xanthophyll. β-β carotene is the only carotene present, zeaxanthin, neoxanthin, and fucoxanthinol are found at the 0.01–0.02% of total carotenoid level (Haugan & Liaaenjensen 1994).

The microalgal cultures were grown in a semicontinuous batch cultivation system, maintained at 20°C (± 2°C) and constantly illuminated and aerated. The growth medium was autoclaved seawater enriched with 1 mL L^{-1} Walnes medium and 0.1 mL L^{-1} vitamin solution. In addition, 0.3 mL L^{-1} of sodium metasilicate (Na_2SiO_3 0.5H2O) was added to the *P. tricornutum* cultures. Before harvest, the cell densities were calculated from haemocytometer counts; cells were harvested when the densities were approximately 1×10^7 cells ml l^{-1}. The algae were separated from their culture media using centrifugation (8,000 rpm, 10 min). Approximately 6–9 L of T-ISO and 3–4 L of *P. tricornutum* cultures were required to yield a soft algal pellet of 4–6 g wet weight. The *L. saccharina* was rinsed in filtered seawater and finely chopped before incorporation into the diets. The dry ingredients and the corn oil were weighed into a beaker, the appropriate amount of water added, and the mixture thoroughly stirred. The mixture was then heated in the microwave for 15 sec, stirred briefly, and then heated for a further 15 sec. It was then allowed to cool to approximately 35 C before adding the algae. Once set, the prepared diets were cut into 1-cm^2 cubes before distribution to the urchins at a rate of one cube $individual^{-1}$ day^{-1}.

TABLE 1.

Diet composition.

Ingredient	Amount	Percentage Wet Weight
Corn oil	0.12 g	7.18%
Dried skimmed milk	0.63 g	4.64%
Casein	0.57 g	7.95%
Gelatine	0.37 g	6.72%
Agar	0.53 g	1.57%
Filtered seawater	25mL/20mL	
Algae	4.5–5g	
	(0 g for control diet)	70.84%

Data Collection and Statistical Analysis

Five urchins from each aquarium were sacrificed at the start of the experimental period (sample day 1, 20 May, 1999) and thereafter at approximately monthly intervals. Whole wet weight (to the nearest 0.001 g) and horizontal test diameter (to the nearest 0.05 mm) were recorded before dissection. Upon dissection, the color of the gonads was assessed immediately by matching it to the closest color in the Pantone® collection of standards (Pantone 1995, Cook 1999). The gonad color was always assessed by the same observer in good natural daylight. Unmarketable shades were dark brown, gray, or black (Pantone colors 4–6, 1545, and 161); acceptable colors were pale yellow and orange (Pantone 155, 156, 713), and the most desirable shades were bright orange (Pantone 123, 136, 149).

The wet weight of the gonad, emptied gut, and eviscerated test were also recorded. Whenever possible, the sex of the individual was determined by examination of extruded gametes, because sex can influence gonad color, ripe males tending to paler colors. The gonad index (GI) was calculated as a measure of gonad growth. An alimentary index (AI) was calculated as an additional indicator of sequestered nutrient stores (Klinger et al. 1998, Kelly et al., 1998b). Indices were calculated using the formulae of Kelly et al., 1998a: GI (or AI) = wet weight of gonads (or gut) divided by the wet weight of the eviscerated test and spines, expressed as a percentage. To allow comparison with GI calculated using total wet weight as the denominator, the GI values quoted here should be divided by a conversion factor of 1.45.

The numerical data were log-transformed and tested for normality and homogeneity of variance (Zar 1996) using MINITAB, version 12.1 for Windows. The log-transformed data were analyzed using analysis of variance (ANOVA) when the assumptions were met, and the Kruskal–Wallis nonparametric ANOVA when violations occurred. Tukey's or the nonparametric Nemenyis (Zar 1996) multiple comparisons tests were employed to assess where the differences occurred in the cases of rejection of the null hypothesis. The observed gonad colors were classified as unacceptable, acceptable, or excellent for marketing. The frequencies of occurrence in each category at each sample date were compared to those expected should the algae have had no effect on color (i.e., those observed in the control group) using the log-likelihood ratio (Zar 1996).

RESULTS

Gonad Growth

A three-way ANOVA incorporating sample date and treatment as fixed factors and replicate tanks nested within treatments showed that there was a significant increase in GI over the duration of the experiment ($F = 64.67$, $df = 2, 16$, $P < 0.001$) (Fig. 1).

Nested (replicate tanks within treatments) ANOVA was used to examine difference in GI between treatments on any given sample day. At the start of the experiment (sample 1), there were no significant differences in gonad index between diet groups. At the end of the experiment, both groups of microalgae-fed (*P. tricornutum* and T-ISO) urchins had significantly higher ($F = 4.0$, $P = 0.013$, $df = 3$) GIs than those fed the control diet. There was no significant difference in GI between urchins fed *L. saccharina* and the control group. The GI produced by *P. tricornutum* became significantly higher than that produced by the control diet after only five weeks; whereas, the effect of T-ISO did not become significant until the end of the trial (after twelve weeks).

Alimentary Indices

There were no significant treatment effects on AI at any time during the experiment (sample 1: $P = 0.754$, sample 2: $P = 0.097$, sample 3: $P = 0.536$, sample 4: $P = 0.424$). There was, however, a significant increase in the AI of all the algae-fed urchins after the first five weeks of the trial (*L. saccharina*-fed urchins: $P < 0.001$, *P. tricornutum*-fed urchins: $P < 0.001$ and T-ISO-fed urchins: $P < 0.001$). The urchins fed the control diet did not show a significant increase in AI until eight weeks into the trial ($P < 0.001$). There was no significant change in test diameter over the duration of the trial ($P = 0.198$) or among diets on individual sample dates ($P = 0.844$).

Gonad Color and Sex Distribution

The gonad color distribution for each treatment at each sample date is summarized in Table 2. At the start of the experiment, there were no differences in color distribution between any of the treatment groups and the control group. However, after five weeks (sample 2), the urchins fed *P. tricornutum* had a significantly better color distribution than those fed the control diet (Table 3). After twelve weeks, the T-ISO fed urchins also had a significantly better color distribution than the control group. The data generated from the control group indicated there was no seasonal change in gonad color over the course of the experiment.

The sex ratios on sample days three and four were determined as the urchins spawned on dissection, and a log-likelihood comparison with the ratio in the control group showed that the male:female ratio for urchins fed the T-ISO diet differed significantly from that of the control on sample days 3 and 4 (Table 4).

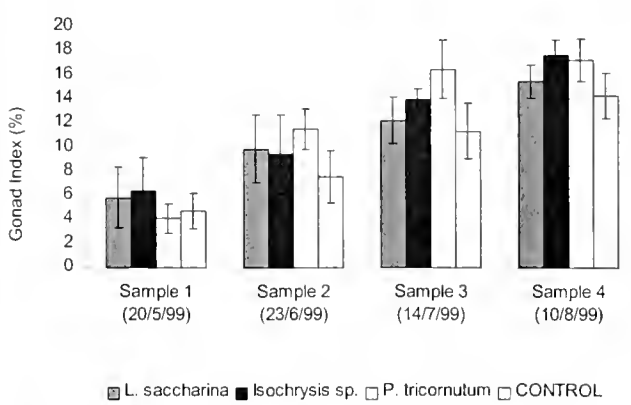

Figure 1. Mean gonad indices at each sample date, with 95% confidence intervals.

DISCUSSION

Gonadal and Somatic Growth

The gonad acts as a nutrient storage organ in *Psammechinus miliaris*; urchins provided with a nutritious food source demonstrate rapid gonad growth because of a proliferation of nutritive phagocytes (Kelly et al. 1998b). The low GIs of the urchins at the start of this experiment suggest that the wild population at the collection site were of a poor nutritional status. Therefore, it is not surprising that the GI in all treatment groups increased significantly over the experimental period, during which they were receiving a constant supply of nutritious food. However, by the end of the experimental period, the GIs of the urchins fed the two microalgal diets were significantly higher than those fed the control diet, implying that the microalgae imparted additional nutritional value for the urchins.

The gonad biomass of many commercially important echinoids shows a strong seasonal variation related to their annual reproductive cycle, resulting in a limited season of economically viable harvest (Byrne 1990, Hagen 1998). This experiment was conducted during the spawning season of *P. miliaris* in Scotland (Kelly 2000) during which gamete release normally results in a steady decline in GI. However, instead of decreasing, the GI increased steadily over the duration of the experiment, indicating it is possible to have an out-of-season gonad yield from *P. miliaris* fed artificial diets enhanced with microalgae.

Despite an approximate threefold increase during the course of the experiment, the mean values of GI obtained for all groups by the end of the trial (14.25–17.64%, $n = 15$) remained lower than the maximum values obtained in other studies on this species in Scotland. Kelly et al. (1998b) found that urchins reared in proximity to Atlantic salmon (*Salmo salar*) in polyculture trials could attain summer GIs of as much as 40%. In laboratory trials, Cook et al. (1998) found that *P. miliaris* fed commercially manufactured salmon food attained a mean GI of approximately 35% in August, which continued to grow for the remainder of the trial, reaching a maximum value of almost 60% by December. The lower values obtained in this trial are likely to be a result of the inferior nutritional value of the microalgal diets, as compared to commercially manufactured salmon food. Although a full comparison of the relative nutritional profile of the algae used was beyond the scope of this study, it is interesting to note that *Phaeodactylum tricornutum* and *Isocrysis* sp. are reported to have a high content of the fatty acid EPA (Otero et al. 1997) and DHA (Fabregas et al. 1995), which may partially account for the enhanced gonad growth of urchins fed these diets. Enhanced gonad growth has been demonstrated for *P. miliaris* fed diets rich in DHA (Cook et al. 2000).

The AI is an additional measure of the nutritional status of echinoids, because it is also a site of nutrient storage (Lawrence et al. 1966, Lawrence & Lane 1982). In this trial, the gut indices of all groups increased significantly during the first five weeks of the trial, further implying that the wild urchins had a low nutritional status at the start of the trial. However, there was no further in-

P. tricornutum	86	7	7	40	0	60	33	7	60	7	40	53

(u = unacceptable; a = acceptable and e = excellent) $n = 15$.

crease in AI over the remainder of the experiment, reflecting either the limited storage capacity of the gut wall (Lawrence & Lane 1982) or the limiting nutritional value of the experimental diets. No significant somatic (test) growth was observed over the duration of the experiment. However Cook et al. (1998) found that adult urchins fed a macroalgal diet increased in test diameter at an average rate of only 0.02 mm/month.

Gonad Color

Relatively few studies have been designed to address the important issue of gonad color in sea urchin production specifically. The measurement and communication of color requires careful attention, and although several studies (Barker et al. 1998, Watts et al. 1998) have noted that differences in gonad color occur in echinoids fed artificial diets, they do not attempt to quantify their comparisons. The use of internationally recognized color standards in the present trial was intended to provide a less ambiguous means of color communication and comparison.

The use of synthetic carotenoid pigments to improve flesh coloration is common in the manufacture of artificial diets for cultured salmonid fish (Storebakken et al. 1987, Foss et al. 1987). However, the cost of synthetic pigments contributes significantly to the production cost of artificial feeds in salmonid aquaculture (Torrissen et al. 1990); therefore, it should be avoided if possible in echinoculture.

Robinson and Castell (2000) have shown that incorporating a spray-dried form of the microalgae *Dunaliella salina*, which is rich in β-carotene, into artificial diets caused a pronounced improvement in gonad color in *Strongylocentrotus droebachiensis*. Goebel and Barker (1998) noted no improvement in the gonad color of *E. chloroticus* when fed β-carotene supplements. This suggests that the form in which the pigment is supplied in the diet also dictates how or if it is later expressed in the gonad. Obviously, it would be of interest to compare the effect of a range of different pigments on the gonad color of a variety of commercially important echinoid species. A detailed comparison of the pigment profiles of urchin gonads of a "good" and "poor" color for each species may also help elucidate the pigment requirements of effective, color-enhancing artificial diets. Pigment expression in the gonad may be linked to factors other than pigment presence alone; for example, lipid content or the presence of gametes.

In the spawning season, the ovaries contain more pigment than the testes (Goodwin 1984). Griffiths and Perrott (1976) have shown that carotenoids are passed from the ovaries to the eggs, and Hallenstvet et al. (1978) subsequently showed that they are then transferred to the larvae. It is thought that these pigments play an important protective role in larval development and biological defense (Kawakami et al. 1998). Consideration of sex ratios is, therefore, important in color comparisons between treatment groups. In this study, it was noted that, in general, the female urchins produced gonads of more marketable colors than males, presumably because of the influence of the pigmented eggs as opposed to sperm. At both sample dates three and four, the sex ratios were effectively the same in the control group and the *P. tricornutum*-fed group, the two groups between which the biggest differences in color were seen. This indicates that the observed improvement in gonad color was not merely attributable to unequal sex ratios in the samples, but was a true effect of the diet. In the T-ISO-fed group; however, there were more males than females at sample day three and then more females than males at sample day four. Because the significant shift in color distribution for T-ISO-fed urchins also occurred between these two dates, this result should perhaps be interpreted with a greater degree of caution.

The results of this trial indicate that the microalga *P. tricornu-*

* Indicates the male:female ratio is significantly different from that of the control group at the given date.
$G_{critical} = \chi^2_{0.05,1} = 3.841$ (Zar 1996).

tum is a better choice for inclusion in artificial diets for sea urchins that the other algae considered. Not only did it result in significantly better gonad growth; it also significantly improved gonad color distribution. Furthermore, the improvement in color occurred in a much shorter time, having important implications for culture if microalgal diets are to be used as preharvest conditioning diets for wild or polycultured urchins. In addition, *P. tricornutum* is exceptionally robust in culture and performs well in semicontinuous culture (Otero et al. 1997). It is not clear at present whether the weakly silicified cell walls *P. tricornutum* (Bold & Wynne 1985) affects the ability of the urchins to assimilate the pigment from the algae or pigment preservation during diet manufacture. Although reported to contain the same carotenoids as *P. tricornutum*, the *L. saccharina* diet did not improve gonad color in comparison with the control. Accurate pigment profiles of the algal cultures actually used to create experimental diets would benefit artificial diet design, because the biochemical and pigment composition of algae can change with nutrient and light availability (Fabregas et al. 1995, Fabregas et al. 1998) and season (Stengel & Dring 1998).

LITTORINE FORAGING BEHAVIOR AND POPULATION STRUCTURE ON A WAVE-EXPOSED SHORE: NON-LINEAR RESPONSES ACROSS A PHYSICAL GRADIENT

TROY C. ADDY AND LADD E. JOHNSON*

Département de biologie and GIROQ, Université Laval, Québec, Québec, G1K 7P4 Canada

ABSTRACT Littorines often use topographical features (e.g., holes, crevices) for shelter. We investigated this behavior (% outside of natural crevices and artificial holes during daytime low tides) over a cross-shore wave force gradient. Whereas maximal wave force (MWF) declined linearly with increasing distance from the low tide mark, percent outside increased along this gradient and reached an asymptotic level (70%) 40 m from the low tide mark. A comparison of seasonal averages of percent outside and MWF showed an abrupt transition between high and low values of percent outside with increasing MWF, but comparisons of daily data were more varied, presumably due to the superimposition of other environmental factors (e.g., desiccation). Contrary to earlier descriptive studies and biomechanical predictions, larger littorines were found in locations closer to the low tide mark where MWF were higher, suggesting that size-limitation from hydrodynamic forces does not occur within the size range studied (1–8 mm) when shelters are available. However, the restriction of littorines to areas near shelters can greatly influence community structure by permitting the development of algal assemblages in exposed locations.

KEY WORDS: gastropods, grazing, heterogeneity, hydrodynamic forces, intertidal ecology, refuges, and size gradients

INTRODUCTION

Ecologists have often examined species over environmental gradients in which specific predictions can be made regarding the responses of the species under study. Recent examples include grazing responses of arctic grasses across a snow deposition gradient (Wegener & Odasz 1997) and predation on a marine snail across an algal gradient (Alfaro & Carpenter 1999). Although this approach can only provide correlative relationships, it is especially useful for examining factors that are difficult to manipulate experimentally.

Striking physical gradients occur in intertidal environments, and the distribution of intertidal organisms (e.g., zonation patterns) is often thought to be a function of physical gradients acting either directly on them or indirectly on their predators or competitors (e.g., Garrity 1984, Takada 1996). One well recognized gradient is "wave exposure," which has been typically examined at sites along the shoreline, e.g., from a headland into a bay (Lewis 1964, Palumbi 1986). Intuitively, a gradient in wave energy should also exist across the shoreline as breaking waves dissipate their energy, but this gradient has never been quantified in rocky intertidal environments.

The biology of intertidal organisms has often been examined with respect to this physical gradient (e.g., Emson & Faller-Fristch 1976, Atkinson & Newbury 1984, Chapman 1994, Britton 1995, Takada 1996). Unfortunately, many studies have only examined the environment at two locations along the gradient, often at the extremes, and then interpolated for intermediate locations. Moreover, wave exposure has rarely been quantified and has usually just been subjectively described as "exposed" or "protected." While the most important aspect of water motion is sometimes unclear for a particular situation (Denny et al. 1985, Denny 1988), a number of investigators have developed techniques for measuring maximum wave forces (Jones & Demetropoulus 1968, Palumbi 1984, Bell & Denny 1994), the parameter of water motion most related to dislodgment.

The risk of dislodgment is thought to influence the biology of littorine snails, the dominant herbivores of many high- and mid-shore rocky intertidal habitats, and both morphological and behavioral traits of littorines have been interpreted as responses to water motion. These include larger relative foot area (Atkinson & Newbury 1984, Trussell et al. 1993), shell morphology (Johannesson 1986, Trussell et al. 1993, Trussell 1997, Boulding et al. 1999), and the use of shelters (Emson & Faller-Fritsch 1976, Raffaelli & Hughes 1978, Atkinson & Newbury 1984, Chapman 1994). This latter behavioral aspect can be quite important in influencing both the density and size frequence of littorinid populations (Emson & Faller-Fritsch 1976, Raffaelli & Hughes 1978, Atkinson & Newbury 1984, Trussell et al. 1993). While the influence of crevices on both the individual behavior and population structure of littorinids has been explored, there has been a lack of attention to the physical environment that allegedly controls the behavior of these snails. Although past studies may have been qualitatively correct in their estimation of "wave exposure," there remains a need to explore quantitatively both the behavior and the physical environment to develop a predictive understanding of the ecology of littorines and intertidal communities.

In this study, measures of the physical environment are combined with ecological data to explore the control of foraging behavior across an environmental gradient. Specifically, we examine the correlative relationship between maximum wave force and the use of crevices across an intertidal shore. Such behavioral studies of intertidal invertebrates are rare, as active behavior usually occurs when the tide is high and researchers are absent. Littorines offer an exceptional opportunity as they are often active during low tide (Jones & Boulding 1999) and are distributed in the mid- and high intertidal zones, thereby permitting prolonged periods for observations.

MATERIALS AND METHODS

The study was conducted at Pointe Métis (48°41′N and 68°02′W) located on the St. Lawrence maritime estuary near Mont Joli in Quebec, Canada. Two sites were used: one consisted of a series of bedrock ridges paralleling the shoreline with consolidated boulders and cobbles between the ridges (Fig. 1; Site 1), the other

was a series of less well-defined ridges with intervening tide pools (Fig. 1; Site 2). Elevated rock surfaces at both sites supported few sessile organisms (algae or invertebrates) due to the annual ice scour that occurs along the shores of the estuary (Archambault & Bourget 1983). Littorine snails, principally *Littorina saxatilis* Olivi, but on occasion *L. obtusata* L., were the most conspicuous animals in this habitat and often aggregated in crevices and holes when not foraging on the open rock surface.

The behavior of littorines was studied along a transect perpendicular to shore at each site. At Site 1, the transect covered approximately 70 m and ran across five distinct ridges. At Site 2, the transect covered approximately 20 m and ran across four ridges. Six specific locations were selected along each transect for observations, each corresponding to a natural feature of the landscape (e.g., a face of a ridge). For the three most seaward locations at Site 1, 30-cm portions of six crevices spaced 0.5–2 m apart were chosen at each location (18 total). At Site 2, three crevices were sampled at the most seaward site and at two mid-transect locations (nine total). For each location, tidal height, distance from the spring low tide mark, orientation and inclination of the rock face were measured as well as the dimensions (average of six measures of width and depth) of each crevice (Table 1). Littorines present within the crevices ("inside") as well as the littorines that were present on the exposed rock surface within 25 cm of the crevices ("outside") were counted, and percent outside calculated as 100×(number outside)/(number inside and outside). The distance of 25 cm was chosen based on earlier observations of browse zones (typically 10–20 cm in width) in the algal mats found at certain locations along the transects (L.E. Johnson, pers. obs.). When other shelters were found within 50 cm of the crevice, only littorines within half the distance between the crevice and the other shelter were counted. Local density was calculated as the number (inside + outside) per cm^3 of crevice volume, calculated assuming a triangular cross-section (i.e.,volume = 0.5 × width × depth × length).

In addition to these naturally occurring but variable irregularities in the rock surface, we created standardized irregularities in early May 1998 by drilling sets of holes at all locations along the transects to control for any variation in the form of the shelters across this shoreline. Again, tidal height, distance, orientation and inclination of the rock face were recorded (Table 1). Each set of holes consisted of three holes 1.3 cm in width and 1 cm in depth (total volume = 4.0 cm^3). Each of the holes within the set was

Descriptive information on natural crevices and artificial holes used at sites 1 and 2 for examining littorine behavior: distance from the low tide mark, tidal height, orientation and inclination from the horizontal of the rock face, as well as crevice depth, width, volume (sets of holes always had a total volume of 4.0 cm^3), and densities (no./cm^3 shelter) for each location.

$^{a-d}$ For densities, similar letters indicate no significant differences between groups for multiple pair-wise analyses of two-factor ANOVA (Table 2) performed for each site separately.

separated by 5 cm in a triangular pattern. Three replicates of these sets of holes were established at each location (except one where six were established as a pilot study of the influence of adjacent algal abundance). For each period of observation, the littorines were enumerated as above, except a distance of 15 cm from the holes was used as holes were usually on rock surfaces with few other irregularities and most littorines were found within this distance.

Littorines were counted daily during the morning low tide for series of 3–7 days during spring tides on an approximately biweekly schedule from May 29 to September 20 in 1998 at both sites and May 30 to August 30 in 1999 at Site 1 only, for a total of 64 days of observations. Limited observations were also made during other periods of the spring-neap tide cycle and during other seasons. Littorines were also visually classified with minimal disturbance into 4 different size categories: 1–2 mm, 2-4 mm, 4–6 mm, and 6+ mm (smaller littorines, < 1 mm, were difficult to discriminate against the rock surface). While littorines are usually sized by shell length, we used shell height as defined by Fletcher (1995) as "the distance of the highest point of the shell above a flat surface upon which the shell is lying with the aperture facing downwards" as this measure appears more relevant to the use of crevices.

To estimate the wave energy gradient along these transects, maximum wave force (MWF) was measured over 24 hr simultaneously at three or four locations that corresponded approximately to a subset of the locations of the shelters (Fig. 1). In 1998, only one measurement was taken at each location (Site 1: locations A, B, C, and E; Site 2: locations A, D, and F) while in 1999 the number was increased to four (Site 1 only) to characterize better the MWF at a given location. Maximum wave force was measured using a simple transducer (Bell & Denny 1994) that consisted of a spring attached to a practice golf ball by monofilament line on which a rubber ring was able to slide. Only forces greater than 2 N were measurable by these transducers. The spring and ring were encased in PVC tubing and attached to the rock using a swivel attached to a screw anchored on a local high point. MWF was measured one day after devices were installed or reset. Such measurements were made simultaneously with behavioral observations on 18 days in 1998 and 23 days in 1999. Data from both sites in both years were used for seasonal comparisons of MWF and littorine behavior, whereas only data from Site 1 in 1999 were used to make daily comparisons. These measures of MWF were intended for relative comparisons among locations and not for estimating the forces experienced by the snails.

Data were analyzed using simple linear regressions or two-way ANOVAs with multiple pair-wise comparison tests (LS Means based on significant interactions when they occurred) for specific differences within significant sources of variation (SAS v. 6.12; SAS Institute Inc. 1996). When data were non-normal or variance unequal, we also analyzed rank-transformed data to confirm results obtained using non-transformed data.

RESULTS

Littorines were abundant the entire length of the transects but were 2 to 6 times denser in holes than in natural crevices based on the volume of the shelters available (Table 1). At Site 1, densities were higher at locations far from the low tide mark except at 40 m, a location with a steep, south-facing slope and a high number of crevices (Fig. 1 and Table 1). Densities along the shorter Site 2 transect were comparable to locations at similar distances at Site 1, but were also higher away from the low tide mark (Table 1). Densities in and around crevices were relatively constant (no significant differences) over the season and between years (Addy 2001). In contrast, after the holes were created in 1998, littorine densities in and around holes increased during the summer season but then stabilized in 1999 (Addy 2001). Littorine size structure varied similarly across both transects with larger (> 4 mm) individuals more abundant at locations near the low tide mark (Fig. 2). The percentage of littorines 2–4 mm remained relatively constant across the sites whereas that of the smallest littorines (1–2 mm) was more variable.

A lower percentage of littorines was found outside of holes and crevices at locations closer to the sea at both sites (Fig. 3). Percentage outside increased away from the low tide mark along both transects but became asymptotic near 40 m along the longer transect (Fig. 3a). This trend occurred for both natural crevices and artificial holes, although the percent outside was much higher around holes, typically double that of natural crevices. Although there were significant differences among different size classes in the percentages found outside of shelters at some specific locations, there were no obvious trends, and no statistical differences were found for pooled data, even when locations closer to the low water mark were analyzed separately from those farther away (Addy 2001).

Maximum wave force (MWF) decreased linearly with increasing distance from the low tide mark in both years, although maximum wave forces differed between the two years (Fig. 4). When seasonal means of MWF and percentage of littorines outside of holes are compared among locations, a nonlinear relationship is seen (Fig. 5) — the percentage outside of holes becomes exceed-

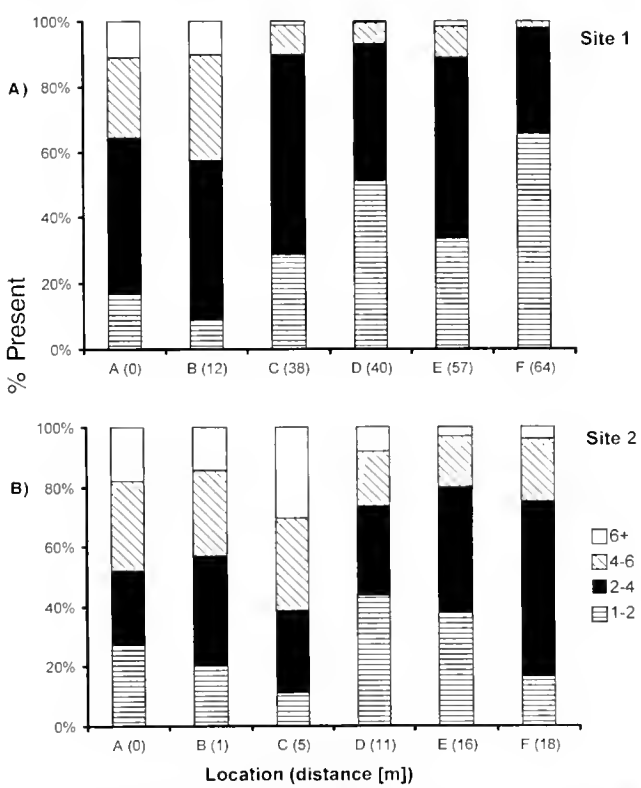

Figure 2. Percentage of each size class at locations of increasing distance from the low tide mark at (A) Site 1 and (B) Site 2.

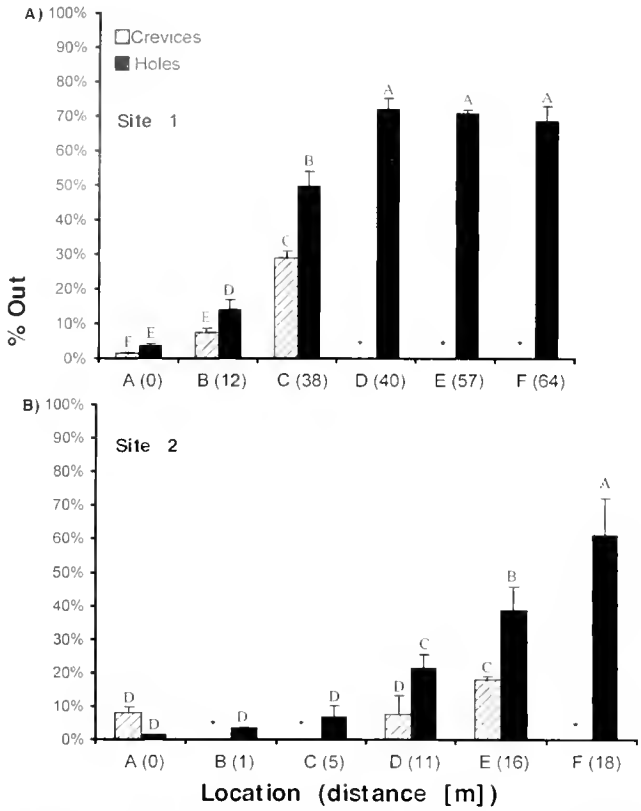

Figure 3. Percentage of littorines found outside of artificial holes and natural crevices at (A) Site 1 and (B) Site 2 for locations at increasing distance from the low tide mark. "*" indicates that crevice data were not collected for those locations. Similar letters indicate no significant differences between groups for multiple pair-wise analyses of two-factor ANOVA (Table 2) performed for each site separately.

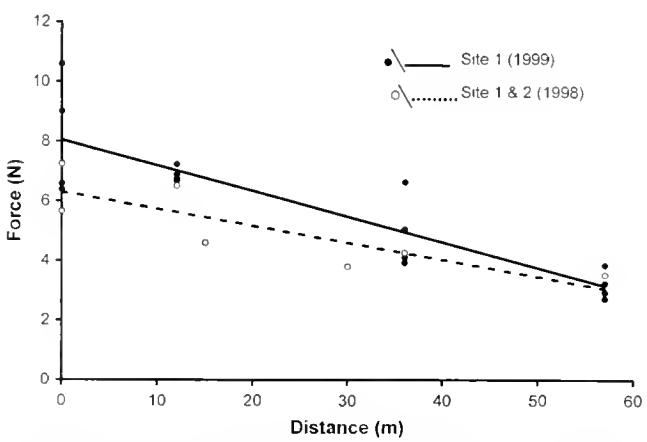

Figure 4. Average maximal wave forces (MWF) as a function of distance from low tide mark. Open circles and dashed line represent average MWF (22 d) for 7 locations (3 at Site 2 and 4 at Site 1) in summer of 1998 (n = 1 for each location); filled circles and solid line represent average MWF (23 d) recorded for four locations at Site 1 in summer of 1999 (n = 4 for each location). Lines represent linear regressions which are both significantly different from zero (1998: r^2 = 0.69, F = 11.4, $p < 0.02$; 1999: r^2 = 0.76, F = 44.5, $p < 0.001$).

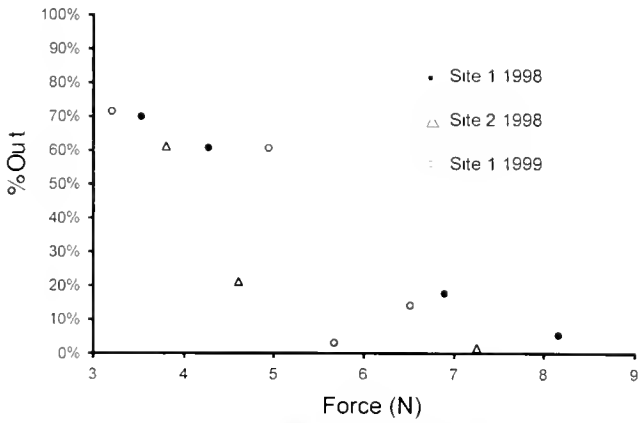

Figure 5. The relationship between the seasonal mean of the percentage of littorines found outside artificial holes and the seasonal mean of the maximal wave force (MWF). Each point represents a different location at Site 1 (1998 and 1999) or Site 2 (1998). Means for MWF in 1998 (n = 22 d) are from one MWF transducer at each location whereas means in 1999 (n = 23 d) are from four transducers at each location.

ingly low (mean < 15%) at locations where mean MWF exceeded a threshold of 5.0–5.5 N. Linear regressions of data above and below this obvious threshold were not significantly different from zero. The relationship between MWF and percent outside is less evident when data for each day are compared for each location (Fig. 6; data from four locations at Site 1 in 1999). Generally, locations closer to the low tide mark had lower values of percent outside, but the data were extremely variable at a given location for a given MWF (Fig. 6). Above a value of 8 N, the percentage outside dropped dramatically and remained near zero. The lowest values of percent outside for each location were obtained during a storm in which MWF exceeded 20 N at the most exposed location (Fig. 6).

DISCUSSION

In temperate environments, the use of crevices is generally thought to be a behavior for reducing the risk of dislodgment by

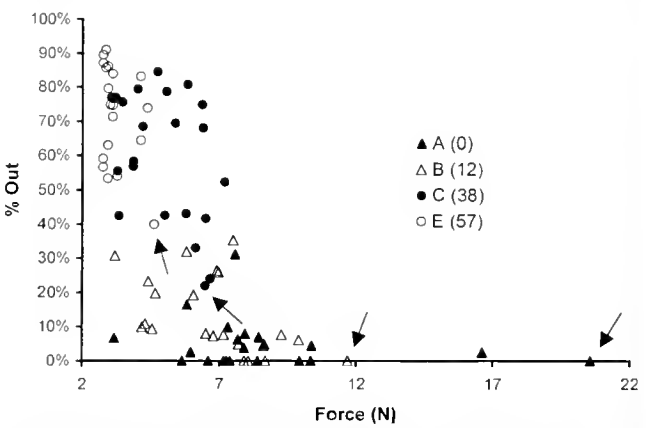

Figure 6. Comparisons of the percentage of littorines outside artificial holes versus maximal wave force (MWF) measured at four locations at Site 1 in 1999. Each point represents the average of three (percent outside) or four (MWF) measurements on a given day (n = 23 d). Values in parentheses on x-axis are horizontal distance from low tide mark. Arrows indicate data taken on the day after a storm.

waves (e.g., Emson & Faller-Fritsch 1976, Raffaelli & Hughes 1978). According to this idea, littorines limit their foraging activities to periods of low tide (Jones & Boulding 1999) and return to shelters to avoid being dislodged by the hydrodynamic forces of the incoming tide. Our results are consistent with this idea—the percentage of littorines foraging (i.e., outside of shelters) was lower in locations of higher maximal wave forces (MWF). An alternative explanation could be that littorines outside of shelters are dislodged at higher rates at locations of higher MWF, which would lead to a lower percentage of littorines outside of shelters but also to a lower local density unless recolonization occurred quickly. While we occasionally observed abrupt decreases in densities at some locations immediately following days of higher MWF, densities were in general quite constant over time (Addy 2001). Thus we interpret this relationship to be due more to behavioral responses (i.e., shelter-seeking behavior) than to demographic processes (i.e., "emigration" by dislodgment).

The relationship between wave force and shelter use is, however, strictly correlative and might be due to other factors. Density, for example, also generally increased with increasing distance from the low tide mark (Table 1). If densities reached a level where shelters were completely filled, then a higher percentage of littorines outside of shelters would occur simply due to a lack of available shelters. Although shelters were sometimes very full, this situation only occurred when values of percent outside were at or near zero. For over 90% of the observations at any given location, numbers of snails inside shelters were less than 75% of the maximum observed for that location (T.C. Addy, unpubl. data). In addition, locations with different densities had similar levels of percent outside (locations C and D at Site 1), and locations with similar densities had vastly different levels of percent outside (locations B and F at Site 2).

The linear decline in MWF with increasing distance from the low tide mark was not matched by a linear increase in the percentage of the littorines outside crevices. Instead, a plateau was reached at approximately 40 m, where MWF averaged 5–6 N, which may represent a threshold below which there is a reduced risk of dislodgment. When percent outside and wave forces were compared among individual days (Fig. 6), this general pattern was still apparent, but there was a great deal of variability in the percentage of littorines outside of shelters at any given location that was not explained by MWF. This variation appears to be related, at least in part to meteorological conditions experienced during low tide (e.g., temperature, desiccation). Other littorines reduce foraging during conditions of high evaporation (e.g. Atkinson & Newbury, 1984, Garrity 1984, Britton 1995), and in tropical environments, desiccation has been suggested as the leading reason for crevice-seeking behavior (Garrity 1984; but see Catesby & McKillup 1998 for the role of predation). We propose that desiccation plays a secondary role here as other field observations (day vs. night) and laboratory experiments (wet vs. dry rocks) support the idea that these littorines avoid conditions of high desiccation (Addy 2001).

Reductions in foraging time in locations of higher wave forces could ultimately have impacts on the population structure of littorine populations, i.e., smaller sizes and reduced densities. Our findings of larger littorines at locations near the low tide mark (Fig. 2) is contrary to this idea and the results of other studies where, if a size gradient existed, smaller littorines were more common close to the low tide mark (Vermeij 1972, Britton 1995 and references therein, Trussell et al. 1993). This trend has been attributed to the reduced susceptibility of smaller littorines to dislodgment (Trussell et al. 1993) and would be consistent with hydrodynamic theory (Denny et al. 1985). However, we examined relatively small littorines, and the trend could be different for larger sizes. Differences in crevice morphology among locations could also explain the trend we observed (e.g., if there were larger shelters in more exposed locations), but our use of artificial holes specifically controlled for this possibility. Thus the underlying cause of the differences in size distribution remains unknown and may be related to differences in local densities and concomitant competition for food. Regardless, the survival of larger littorines in more exposed locations may depend more on a shelter-seeking behavior that allows littorines to avoid hydrodynamic forces that might dislodge and displace them, thereby obscuring any relationship that might exist between size and the probability of dislodgment if shelters were not present. These littorines may be using crevices much like soldiers use foxholes when under fire.

An assessment of the relationship between wave force and littorine density is more difficult because the local abundances we report (i.e., number per unit volume of shelter) do not necessarily reflect the overall density of littorines at these locations or sites. This limitation notwithstanding, we saw increased local densities at locations farther from the low tide mark, which is consistent with the reduced probability of dislodgment there. Other factors (e.g., food supply, recruitment, densities of shelter) may also be acting. Likewise, marked differences in densities were observed over only several meters (Table 2: Location C vs. D, Site 1), suggesting again that other ecological processes are affecting densities.

Differences were observed between crevices and holes with regards to both local density and the percent outside of the shelters: holes sheltered more individuals for a given volume and those individuals appeared more likely to leave shelters during day-time low tides. Potential explanations for these differences are not obvious. The holes were a recent addition to the landscape, and thus were colonized by more actively moving individuals, which may also have been more likely to emerge during low tide. Regardless, the nature of the shelter (e.g., dimensions and location relative to other shelters) appears to have a strong influence on littorine foraging.

In this study, we have measured only a population-level response of littorines along a wave exposure gradient; thus an interpretation of individual responses is problematic. Without knowing the identity of individual snails, it is impossible to determine if the fraction of the population found outside of the shelter from day-to-day represents the same group of high risk-taking individuals, alternating subsets of the population, or a combination of the two possibilities. Still, the fact that some littorines stay inside shelter during periods when others leave is puzzling. This observation supports the idea that littorine behavior is likely to be a complex response to both environmental factors and physiological state (Jones & Boulding 1999), and we suggest that the risk of dislodgment interacts with more basic drives such as hunger or digestive processing in producing these patterns of behavior.

If the hydrodynamic environment is indeed controlling littorine behavior, it may also be indirectly affecting other elements of the intertidal community. At locations with high MWF, where the local densities of littorines and the percentage foraging are lower, green algal mats form when shelters are sufficiently sparse (i.e., more than approximately 30 cm apart). Although there may also be direct effects of water motion on these algae (e.g., wave splash reducing desiccation or higher turbulence increasing nutrient trans-

port), the reduced number of foraging littorines observed in areas of high wave action must contribute substantially to this phenomenon. However, additional quantitative documentation of the direct and indirect interactions of this community is needed to permit the development of a more predictive understanding of its nature.

ACKNOWLEDGMENTS

This research was financially supported by grants from NSERC (Canada) and from FCAR (Québec) to LEJ. We thank Adcou, Inc. for assistance with logistic support. Pierre Frechette and Marie Lescroat for assistance in the field, John Himmelman and Helga Guderley for fruitful discussions, and Gaétan Daigle for statistical counsel. We also appreciate the efforts of Joe Britton and Bob McMahon in organizing the Sixth International Littorinid Biology Symposium where this work was initially presented. This paper is a contribution to the research program of the Groupe Interuniversitaire de Recherches Océanographiques du Québec (GIROQ).

CONTRASTING LIFE HISTORIES AND DEMOGRAPHIES OF EIGHT SPECIES OF LITTORINES AT NINGALOO REEF, WESTERN AUSTRALIA

ROBERT BLACK* AND MICHAEL S. JOHNSON

Department of Zoology, University of Western Australia, Nedlands, Western Australia, 6907 Australia

ABSTRACT This study considers four species of littorines from rocky shores (*Nodilittorina australis*, *N. millegrana*, *N. trochoides*, and *Littoraria undulata*) and four species from mangroves (*L. cingulata*, *L. filosa*, *L. scabra*, and *L. sulculosa*) between July 1989 and June 1999. We conducted periodic censuses of the same replicate areas at four rocky shore sites spread over 40 km of shoreline and at the same replicate mangrove trees in four groups at sites at the opposite ends of a bay, about 2 km apart. This design allowed us to partition the variability in abundance of each species into components associated with the sites, sampling units within sites, time of sampling, sites × times of sampling, and the residual. The littorines of the rocky shores had the greatest variability associated with differences among the four sites for the total populations and among sites and sampling times × site for recruits, whereas the littorines of the mangroves showed the greatest variability associated with times of sampling and sites × times of sampling. We also conducted shorter-term mark and recapture studies to provide direct evidence about growth and survivorship of these snails. All three species of littorines from mangroves with sufficient recaptures showed rapid growth, reaching half their maximum size in 0.94, 0.35, and 0.75 y for *L. cingulata*, *L. filosa*, and *L. scabra*, respectively, and attaining maximum lengths of 22 to 27 mm. The littorines of the rocky shores all had slower growth than those from the mangroves and were all smaller in maximum size, from 10–17 mm. With the exception of *N. millegrana*, which took only 0.50 y to reach half maximum size, the snails on the rocky shores took much longer to reach half their maximal lengths than those in the mangroves (1.23, 2.87, and 1.28 y for *N. australis*, *N. trochoides*, and *L. undulata*, respectively). Patterns in survival parallel the estimates of times to reach half maximal size. We never recaptured *N. millegrana* over intervals as long as 1 y, but some *N. trochoides* marked in 1988 were still alive in 1995. This long-term study of eight similar species in a single geographic area highlights the variability in life histories and demographies of littorines.

KEY WORDS: *Nodilittorina*, *Littoraria*, spatial, temporal, abundance, growth, survival

INTRODUCTION

Littorine snails are such an abundant and conspicuous feature of upper intertidal marine habitats worldwide that they are the subjects of intensive and extensive taxonomic, ecological, evolutionary, physiological, and behavioral research (McQuaid 1996a, McQuaid 1996b). Nevertheless, ecological investigations of littorines, in common with almost all ecological studies, suffer from two shortcomings. First, most studies are of short duration, as pointed out for ecological studies in general by Tilman (1989). Although there are some exceptions involving short-lived species (e.g., Underwood & McFadyen 1983, Williams 1992), most population ecological studies do not last as long as the generation time of the littorines under investigation. Brown (1998) explained how the continuation of his studies on desert rodents revealed that interesting changes will always occur and need to be studied in long-term experiments. Second, there has been a geographic and associated taxonomic bias. Reflecting the majority of researchers, most studies have been in temperate Europe and North America dominated by the genus *Littorina*. Southern hemisphere and tropical littorines of the genera *Littoraria* and *Nodilittorina*, with important exceptions (e.g., Reid 1986), have not been as extensively and thoroughly studied (Davies & Williams 1998), and as pointed out by Underwood and Denley (1984), there are difficulties inherent in automatically applying the paradigms developed in one geographical area to another.

This long-term observational study of the population dynamics and life histories of littorines in tropical, northwestern Australia begins to address these issues of location and duration of study. By selecting Ningaloo Marine Park as a study site, we were able to study in one small area four species on mangroves and four from the rocky shore, of which three species are endemic to Western Australia. By returning to the same mangrove trees and sections of rocky shore at irregular intervals over a decade, we have been able to document spatial and temporal variability in abundances of each species over a time that exceeds the estimated maximum age of most littorines (Powell & Cummins 1985, Heller 1990). By performing simple mark and recapture studies, we have been able to estimate rates of important demographic processes. Thus, the objectives of this study were to (1) quantify the spatial and temporal variability in abundance of the eight species and of their recruitment and to examine the concordance of the temporal patterns in abundance, (2) estimate rates of growth and survival and so document the diversity of rates of these processes in relation to the changes in abundances, and (3) examine covariation in life-history characteristics.

MATERIALS AND METHODS

Study Sites

Our study sites were in the Ningaloo Marine Park in northwestern Western Australia (22°S, 114°E) (Fig. 1). We studied mangrove littorines in Mangrove Bay, a 2-km-wide bay with scattered *Avicennia marina* along its sandy shoreline. Except for a few trees at Yardie Creek, 40 km to the south, these mangroves are the last concentration of mangroves associated with the extensive stands in Exmouth Gulf to the east and are separated by 400 km from others at Carnarvon to the south. In fact, Reid (1986) indicated the absence of any species of mangrove littorine at Mangrove Bay, so their presence raises the question of the spatial and temporal variation in their distribution and abundance.

Rocky shores are more widespread, so we were able to study rocky-shore littorines at four locations spanning 22 km in Ningaloo Marine Park (Fig. 1). The rocky shores consist of horizontal

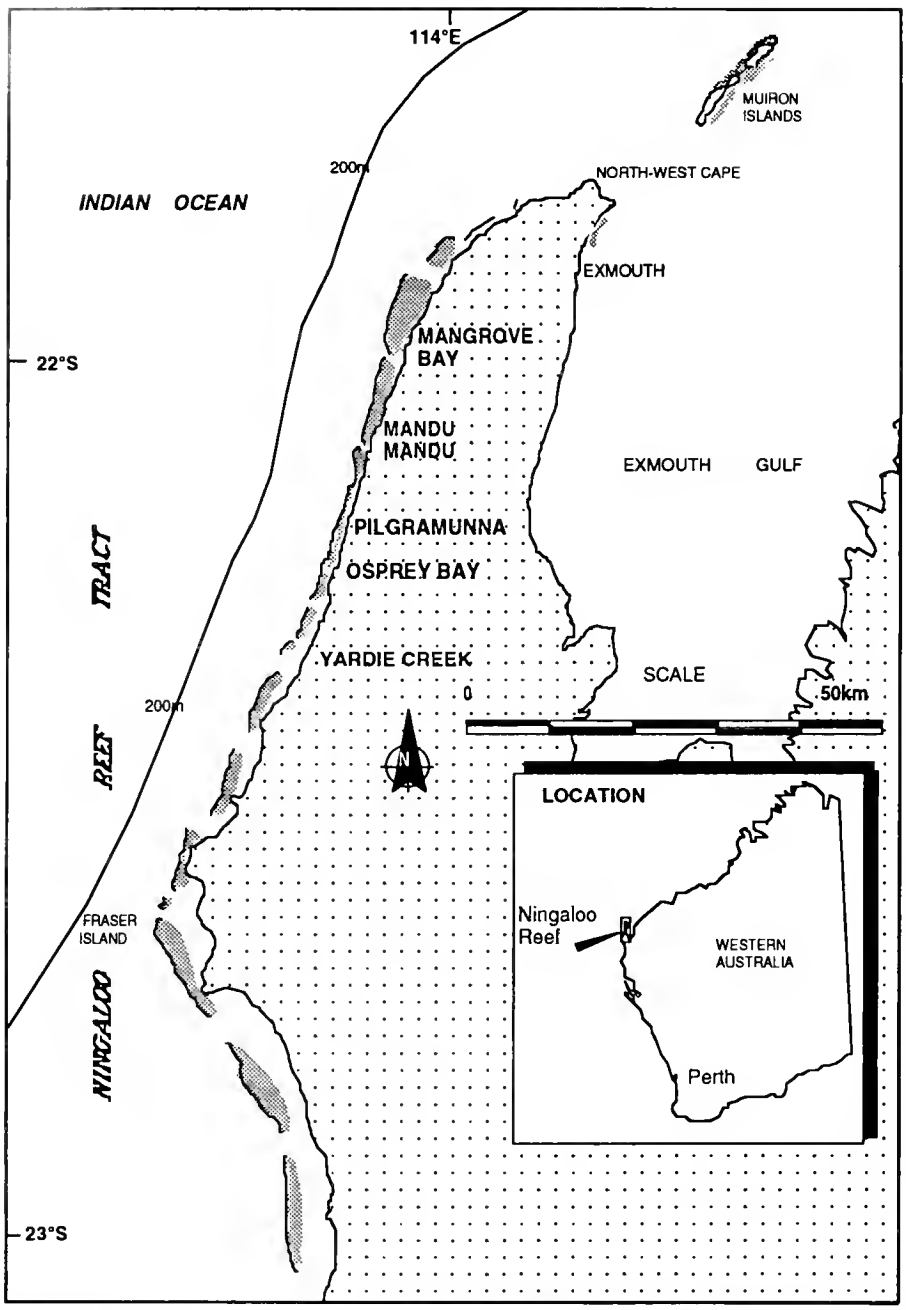

Figure 1. Map showing the five study sites on the mainland shoreline of Ningaloo Marine Park. We censused four species of mangrove littorines at Mangrove Bay and four species of rocky-shore littorines at Mandu Mandu, Pilgramunna, Osprey Bay, and Yardie Creek. The map also shows the discontinuous sections of fringing coral reef as a line for the reef crest, backed by the reef flat in stippling.

intertidal platforms that terminate in nearly vertical steps in the limestone up to 2.5 m high. The littorines live in the upper portion of the step and extend a small distance beyond the edge of the step. Each site consisted of several adjacent 1-m-wide vertical transects with a top horizontal portion that included the upper limit of distribution of the littorines and a larger vertical section that extended below the lower limit of distribution. The main site was at Mandu Mandu, which we chose because we had observed high densities of four species of littorines in 1987. The site was three adjacent 1-m-wide transects 9 m in length. The transects had a gently sloped upper section, a middle section of large blocks of rock, and a lower section of rock projecting from a cobble-covered, horizontal platform. The other three sites were south of Mandu Mandu at locations of easy access where in October 1988 we found sections of rocky shore with reasonable densities of most of the rocky-shore littorines. At Pilgramunna, Osprey Bay, and Yardie Creek, respectively, we censused four, five, and five adjacent 1-m-wide transects that included the upper 1.5-m portion of the step in the rock and extended up to 2 m along the horizontal rock at the top of the step.

Species

We studied four species of mangrove littorines that all have northern distributions within Australia and are close to their south-

ern limit of distribution at Ningaloo Marine Park. *Littoraria cingulata* (Philippi, 1846) and *L. sulculosa* (Philippi, 1846) are Western Australian endemic species and are difficult to distinguish as small recruits, although diagnostic features are obvious in larger individuals. *L. filosa* (Sowerby, 1832) and *L. scabra* (Linnaeus, 1758) have widespread Indo-West Pacific distributions. The mangrove snails have relatively thin shells, which are delicate compared with their robust rocky-shore counterparts. *L. filosa* and *L. scabra* are ovoviparous with planktotrophic larvae (Reid 1989), and because *L. cingulata* is in the same subgenus (Littorinopsis), it is assumed to be ovoviparous too (Reid 1986). *L. sulculosa*, in the subgenus Palustorina, is assumed to have oviparous development (Reid 1986). Most individuals of all four species live on the twigs and small branches of the mangrove trees, but *L. filosa* lives also on leaves, and *L. scabra* live also on large branches.

Four species of littorines were common at the rocky-shore sites. *Nodilittorina australis* (Gray, 1826), another western species endemic to Western Australia, were found at Mandu Mandu in two morphological forms previously recognized as two species (Rosewater 1970) but which clearly are a single species with a plastic morphology (Johnson & Black 1999). The three other species, *N. millegrana* (Philippi, 1848), *N. trochoides* (Gray, 1839), and *L. undulata* (Gray, 1839), live in northern Australia and the Indo-West Pacific (Rosewater 1970, Wilson 1993). A fifth rocky-shore species, *N. unifasciata* (Gray, 1826), which has a southern distribution in Australia, appeared sporadically at some of our sites but was too rare to provide consistent information. The four abundant species were easily distinguished by the external characteristics of the shells and by their distribution on the shore. *N. trochoides* appeared on the high part of the shore, and *N. millegrana* appeared on the low part. *N. australis* occupied intermediate levels of the shore, overlapping with the highest *N. millegrana*. *L. undulata* also occurred at intermediate levels of the shore, overlapping with the lowest *N. trochoides* and the highest *N. australis*. *N. millegrana* and *N. trochoides* spawn single ova in pelagic cupola capsules, and their development is planktotrophic; *L. undulata* is identical except for having a biconvex disk capsule (Reid 1989). *N. australis* is thought to be oviparous (Rosewater 1970). Thus, in all eight species studied, recruitment was from planktonic larvae.

Sampling Scheme

Sampling was conducted in two phases. The first phase emphasized the spatial and temporal variability of the recruits. Between October 1988 and June 1991 we made twelve, approximately quarterly, visits to our rocky-shore sites in which we estimated the abundances of recruits by collecting them from the sites. We began collecting the recruits from the mangrove trees in March 1989 so that the number of censuses of the mangrove littorines was only eight. We did not return the recruits from the rocky shores for any of the twelve censuses, but we did return the recruits on the mangroves in the last three censuses. The other phase of our sampling involved censuses of all littorines before (June 1988, rocky shore only) and after (June in 1991, 1993, 1995, and 1999, rocky shore and mangroves) our intensive censuses of recruits. Although we had censuses of total snails for some of the visits when we removed recruits, we excluded those censuses from analyses that quantified the spatial and temporal variability of the total populations. For the total populations, we had five censuses of rocky-shore total populations and eight censuses of mangrove unaffected by our collections.

Our basic sampling unit at the mangrove site was a mangrove tree, but there was further structure to the data because there were four groups of trees. At the northern end of Mangrove Bay, trees A, B, and C formed one group and were 50 m offshore from two pairs of trees (D and E, and F and G). Trees in each of these three groups had branches that overlapped. The fourth pair of trees, H and I, were separated by about 200 m and were at the southern end of the bay about 1.5 km from the other groups. Thus, trees were nested within groups and represent spatial heterogeneity at the smallest spatial scale at which we sampled. Groups of trees represent spatial heterogeneity within Mangrove Bay. When we conducted censuses of recruits or of total snails during low tides, we made careful searches of all the surfaces of all the leaves, twigs, small stems, branches, and main trunks of the trees, using both sight and touch, and collected each individual. We made some preliminary detailed recordings of the microhabitats in which each individual snail was located, which helped us appreciate exactly where snails lived on the mangrove plants. We usually searched the trees twice, looking at the leaves and branches from different directions, but our searches were not 100% efficient, as judged by our discovery of a few missed snails when we returned snails after measuring them. We measured the length of each snail to the nearest 0.1 mm with calipers and returned all the snails, usually on the next day. Wetting the snails made them active, and they readily clung to or stuck with mucus to surfaces on which they were placed.

At the four rocky-shore sites, our basic sampling unit was a 1-m-wide strip of rocky shore that spanned the vertical range of distribution of the littorines. At all the sites the replicate strips were adjacent to each other and were nested within the site; they were therefore comparable to the trees sampled for mangrove littorines. The sites sampled for rocky shore littorines were separated by 5 to 22 km so that the spatial heterogeneity represented by sites was at a much larger scale than for groups of trees at Mangrove Bay (Fig. 1). Our censuses were conducted at low tide, using fine forceps to pick up the tiny recruits and to extract snails from crevices. We searched each area from different angles, attempting to find all the snails. We measured the snails by shaking them through a series of sieves with holes in 0.5-mm increments, from 2.0–10.0 mm, and counting the numbers retained on each sieve. We returned the snails, except for the recruits from sieves 3.5 mm and smaller, in the quarterly samples to the vertical section within each 1-m strip from which they had been collected. We wet the snails to activate them and splashed water on the shore so that the snails could reattach themselves before the next high tide.

Statistical Analysis

Our sampling scheme involved three main factors, representing spatial and temporal variation. The basic experimental unit was a mangrove tree or a 1-m-wide strip of rocky shore. These were nested within group (for the mangrove littorines) or site (for the rocky shore). We repeatedly sampled the same experimental units at different times (quarters for the recruits and years for the total populations), so the model also included a term representing the interaction between the spatial and temporal terms. This was a repeated measures design with between-subjects terms involving the spatial factors and the within-subjects terms involving the temporal factor and the interaction term. In our view, all the factors in this sampling design were random because we were not concerned with the particular sites or specific times of sampling. Table

TABLE 1.

Model for the analysis of variance for the sampling scheme.

Source	G	Degrees of freedom MC	MR	RSC	RSR	Components in the test denominator
Between subjects						
S	a − 1	3	1	3	3	residual + subject (S) + T × S
Subjects (S)	a (r − 1)	5	3	13	13	residual
Within subjects						
T	b − 1	7	7	4	11	residual + T × S
T × S	(a − 1) (b − 1)	21	7	12	33	residual
	residual a(r − 1) (b − 1)	35	21	56	143	

The model involved a levels of the random spatial factor (S) and b levels of the random temporal factor (T), with repeated measures taken on r replicates of the experimental units (subjects) nested within the spatial factor. The degrees of freedom are shown for the mangrove (M) and rocky shore (RS) samples for each of the complete censuses (C) and the counts of recruits (R) as well as the general case (G) for a balanced design. The components of the test denominator are the synthesis produced by the statistical program JMP (SAS Institute, Cary, NC); each analysis will have particular coefficients associated with each term.

1 shows the terms of the model and the components in the denominator of the F test for each term. We used the Fit Model procedure of the JMP Statistical Discovery Software (SAS Institute, Cary, NC) to perform the repeated measures analysis of variance (ANOVA) of the model with all the factors as random and to calculate the variance component for each term in the model. We present these variance components as a percentage of the total variance and show the statistical significance of the terms.

Survivorship and Growth Rates

On eight occasions for the mangrove snails and on five occasions for the rocky shore snails we marked groups of snails with Humbrol Enamel model paint, using different colors as a code for the time of marking. After drying the shell, we painted the margin of the aperture, as illustrated in Behrens Yamada (1989, Fig. 2). For the recaptured snails the position of the paint delineated the margin of the aperture permitted measurement of the size at which the snail had been painted. We used the total length to the nearest 0.1 mm at painting and at recapture and the time interval in years (t) between marking (coded by the color or paint) and recapture to provide estimates of von Bertalanffy growth equations as overall summaries of growth. We used the nonlinear fit procedures of the JMP software to obtain estimates of the von Bertalanffy parameters: $L\infty$ (asymptotic size) and k (growth coefficient) in fitting the function, increment in length = $[L\infty - \text{initial length}][1 - e^{(-kt)}]$.

We used the regression of the natural logarithm of numbers of marked snails recaptured on time in years after initial painting to estimate the instantaneous rate of mortality and converted that to finite annual rate of survival. Similar methods of marking littorines and calculating growth and survival have been used and described in detail by Hughes and Roberts (1981).

RESULTS

Spatial and Temporal Variation of Abundances of Mangrove Littorines

During the eight censuses of the total numbers of littorines on individual trees, each species was absent from each of the trees at least once, except for *L. filosa*, whose lowest abundance was as a single individual on tree H. *L. sulculosa* was completely absent from trees B, E, and F and was the least common of all the species on the other trees, averaging a maximum of only 4.5 on the six occupied trees. In contrast, *L. filosa* was usually the most abundant, with a maximal abundance of 349 on tree H and an overall average maximum abundance on all trees of 130.5. Comparable figures were 165 and 50.2 for *L. scabra* and 73 and 16.7 for *L. cingulata*. Therefore, there was considerable spatial and temporal

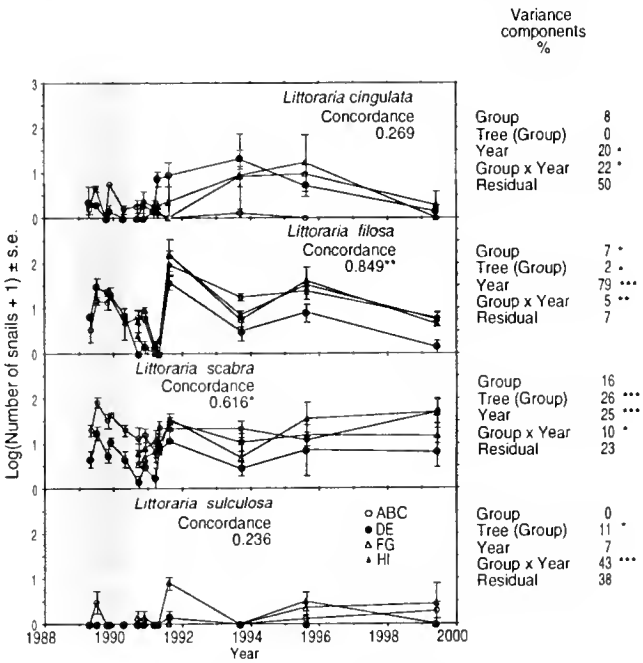

Figure 2. Mean abundance (±SE) of four species of littorines on four groups of mangrove trees at Mangrove Bay, on twelve occasions between April 1989 and June 1999. The shaded area of the plots represents times when our collection of recruits influenced the abundance of the snails; these times are not included in the analyses of concordance or the variance components. Groups ABC and DE were censused at all the times, but censuses began in August 1990 for groups FG and HI. Lines join the points for each of the four groups. The total numbers of snails censused were 308 *Littoraria cingulata*, 1,963 *L. filosa*, 1,869 *L. scabra*, and 47 *L. sulculosa*. The coefficients of concordance among species within a group of trees were ABC 0.069; DE 0.496; FG 0.449; HI 0.611. *$P < 0.05$; **$P < 0.01$; ***$P < 0.005$ for coefficients of concordance and F tests associated with the terms in the analysis of variance.

variability in the abundances of these snails in our sample of mangroves.

Figure 2 shows the average of the logarithms of the counts of snails of each species for the four groups of trees and provides two quantitative summaries of the spatial and temporal variability for the eight censuses when we were not collecting and removing the recruits (unshaded portion of the figure). The first summary is the value for the Kendall coefficient of concordance (Siegel 1960). For the values listed for each species, this represents the correlation between the averages for each group of trees across the eight censuses and therefore indicates whether the abundances on the four groups of trees changed in concert. The abundances of *L. filosa* and *L. scabra*, the two most abundant species, were significantly concordant judged by this statistic and as indicated by the few crisscrosses of lines joining the census values for each group of trees. For the values for concordance listed in the caption of Figure 2 for the four groups of trees, which tests whether the four species fluctuated in concert over time in each group, only trees H and I showed significant concordance. Thus, these analyses indicated that *L. filosa* and *L. scabra* had synchronized temporal fluctuations across the 1.5 km spanned by the four groups of trees, but because the species were not concordant in three of the four groups, the temporal patterns were not consistent among species.

The second summary of temporal and spatial variability in Figure 2 is the variance components. The percentage values shown for each term in the model of our sampling scheme sum to 100% for each of the species. The clearest result was for *L. filosa*, which extends the result from the analysis of concordance. The term for year had the largest variance component at 79%, indicating that temporal variation contributed most of the variability, and the term for group × year was low, indicating that the four groups varied in concert over time. The variance components for *L. scabra* also had a relatively high value for year and a relatively low value for group × year, as expected from the significant index of concordance, but the three other terms in the model contributed substantially to the total variance as well, represented in Figure 2 by the separation of the group averages at each time, the crisscrossing of the lines, and the large standard errors. The variance components for *L. sulculosa*, the least abundant species, had the most variability explained by the group × year term and the residual term. *L. cingulata* differed from the other species in having the residual term contribute most of the variation (represented on the figure by the standard errors associated with each point, which indicates the tree × group [tree] × year interaction). The final important point about the variance components is that the distribution of variance among the terms of the model was different for each species, indicating that, at the scales represented by the spatial distribution of the groups of trees and by the trees within groups, the abundances of four species varied independently.

Figure 2 shows information for five censuses not included in the previous analyses because we collected and retained the recruits (grayed area of figure). One striking feature of these data for the two most abundant species, *L. filosa* and *L. scabra*, was the general decline in the average total abundance in the groups of trees ABC and DE. This suggests that the supply of new individuals may determine abundance in these populations and focuses attention on the dynamics of recruitment.

The detailed information on the abundance of recruits came from eight censuses of recruits on five trees. Because the recruits of *L. cingulata* and *L. sulculosa* are indistinguishable, they are pooled in this set of data, which therefore consists of 120 observations. Recruits were rare, because 105 of these counts were zero. Recruits of *L. scabra* had the highest average of 6.8 per tree, followed by *L. cingulata/sulculosa* with 2.0 and *L. filosa* with 0.4, but as Figure 3 shows, there was considerable spatial and temporal variability.

Even though the coefficients of concordance were large, the power of this nonparametric test was low, so none of the coefficients were statistically significant (Fig. 3). However, the patterns suggested by the coefficients of concordance were revealed clearly by the variance components. The temporal coherence suggested for the species, except for *L. filosa*, were indicated by high contributions to variance by the quarter term in the analysis of variance and by the group × quarter term for the pooled species. The two groups of trees contributed substantial variance too, with the offshore group ABC having more *L. scabra* and fewer *L. cingulata/sulculosa* than the inshore group DE. The variance components for *L. filosa* were dominated by the contribution of the residual term, indicating the difficulty of detecting spatial or temporal pattern for the few recruits. In short, although the spatial and temporal scales differed between the data for recruits and total snails, the nature of the spatial and temporal variability was similar: the recruits of the species varied independently of each other over space and with time, and low numbers of recruits appeared sporadically.

Spatial and Temporal Variation of Abundances of Rocky-Shore Littorines

L. undulata was the least abundant of the four species on the rocky shores, averaging about six individuals per 1-m strip across the four sites and five censuses not influenced by our collection of

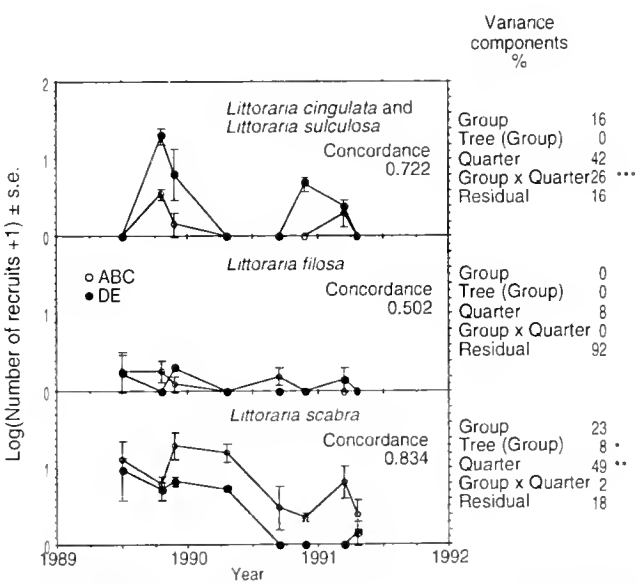

Figure 3. Mean abundance (±SE) of recruits of littorines on two groups of mangrove trees at Mangrove Bay on eight occasions between June 1989 and March 1991. Lines join the points for each group. The total numbers of snails censused were 79 *Littoraria cingulata* and *L. sulculosa*, 16 *L. filosa*, and 273 *L. scabra*. The analyses of concordance and variance components use all the data shown in this figure. The coefficients of concordance among species within a group of trees were: ABC 0.429 and DE 0.410. *$P < 0.05$; **$P < 0.01$; ***$P < 0.005$ for coefficients of concordance and F tests associated with the terms in the analysis of variance.

recruits. It was absent from Pilgramunna on all five censuses and from Osprey Bay on one census. *N. trochoides* and *N. australis* were the most abundant, averaging 66 and 55, respectively, and *N. millegrana* was intermediate at 16. Mandu Mandu had the highest average abundance per 1-m strip of each species and the highest abundance of snails summed over all species on each date.

As judged by the coefficients of concordance in Figure 4, of the four species only *N. trochoides* had significant temporal patterning among sites, and only Mandu Mandu had significant temporal patterning among species. However, the variance components from the ANOVA revealed one consistent pattern among the species: the site term formed the largest percentage for all four species, and more than half for *N. trochoides* and *L. undulata*, reflecting the consistently greater abundance at Mandu Mandu. Furthermore, for these two species, the year and year × site components together were only 18%, indicating considerable spatial and temporal consistency despite statistically significant interaction terms, as seen by the different average abundances at the sites and lack of crisscrossing of the lines joining the data points. A second consistent feature of the variance components was the low percentage associated with the strip within site term, that is, between the adjacent 1-m-wide strips of the shore. *N. australis* had the largest value at 14%, and *L. undulata* the lowest at 0%. In brief, for the rocky shore littorines, large-scale (between-sites) spatial variability dominated and, except for *N. australis*, exceeded temporal variability.

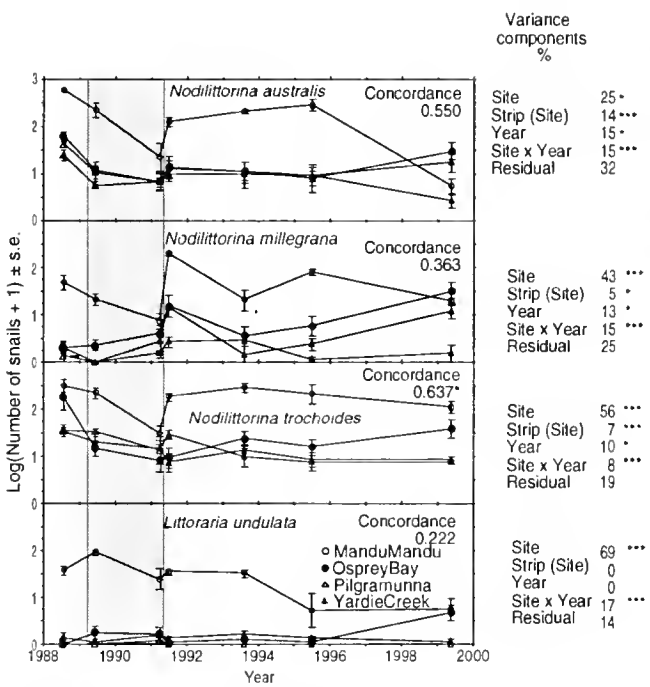

Figure 4. Mean abundance (±SE) of four species of littorines at four rocky shores in Ningaloo Marine Park on seven occasions between June 1988 and June 1999. The shaded area of the plots represents times when our collection of recruits influenced the abundance of the snails; these times are not included in the analyses of concordance or the variance components. Lines join the points for each of the four sites. The total numbers of snails counted in these censuses were 6,506 *Nodilittorina australis*, 1,856 *N. millegrana*, 7,905 *N. trochoides*, and 795 *Littoraria undulata*. The coefficients of concordance among species within sites and the number of strips (in parentheses) were Mandu Mandu 0.536 ($P < 0.05$) (3); Osprey Bay 0.312 (5); Pilgramunna 0.378 (4); and Yardie Creek 0.437 (5). *$P < 0.05$; **$P < 0.01$; ***$P < 0.005$ for coefficients of concordance and F tests associated with the terms in the analysis of variance.

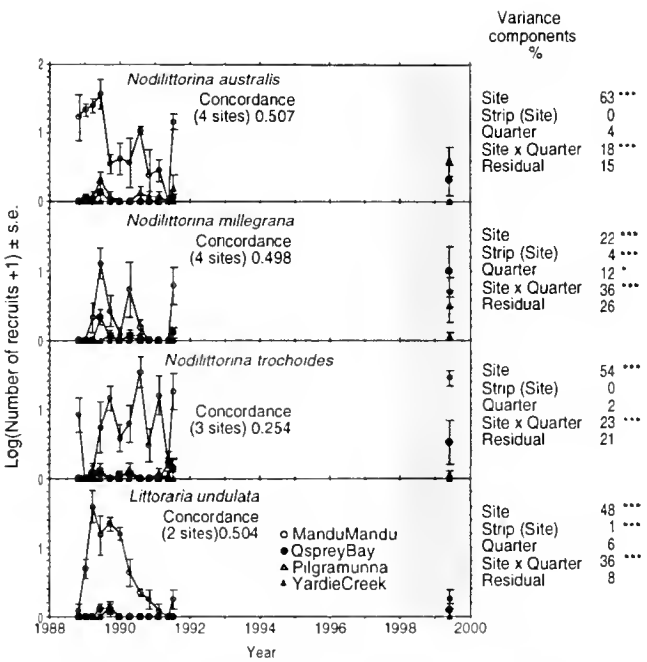

Figure 5. Mean abundance (±SE) of recruits of four species of littorines at four rocky shores in Ningaloo Marine Park on twelve occasions between October 1988 and July 1991. The shaded area of the plots, a census in 1999, was not included in analyses of concordance or variance components. Lines join the points for each of the four sites. The total numbers of snails counted in censuses were 514 *Nodilittorina australis*, 126 *N. millegrana*, 440 *N. trochoides*, and 389 *Littoraria undulata*. The analyses of concordance and variance components use all the data shown in this figure. The coefficients of concordance among species within a site and the number of strips (in parentheses) were Mandu Mandu 0.415 (3), Osprey Bay 0.344 (5), Pilgramunna 0.191 (4), and Yardie Creek 0.143 (5). *$P < 0.05$; **$P < 0.01$; ***$P < 0.005$ for coefficients of concordance and F tests associated with the terms in the analysis of variance.

The gray area of Figure 4 indicates the censuses influenced by our collection of recruits, and as for the mangrove littorines, the downward sloping lines for the total abundances suggested that the removal of recruits may have led to decreases in populations for some of the species at some of the sites. The abundances of these recruits are shown in Figure 5 for censuses during late 1988 to mid 1991.

In the twelve censuses of the four species at the four sites, all species had no recruits on at least one of the quarterly sampling times, and for *N. australis* and *N. millegrana* recruits were never recorded at Yardie Creek; in all, 120 of the 192 observations were zero. Averaged over all sites and quarters, the average abundance of recruits ranged from 2.5 for *N. australis* to 0.6 for *N. millegrana*, with *N. trochoides* and *L. undulata* intermediate at 2.15 and 1.90 per 1-m-wide strip, but these values are largely influenced by the high recruitment at Mandu Mandu (Fig. 5).

None of the coefficients of concordance was statistically significant, and all were less than 0.55, so there were no strong temporal patterns of abundance. As for the analysis of the variance components of the total abundances, the percentage for the site term was about 50% for all species except *N. millegrana*, so spatial variability, at the scale of tens of kilometers, dominated the abundance of recruits (Fig. 5). The abundance of recruits was greatest

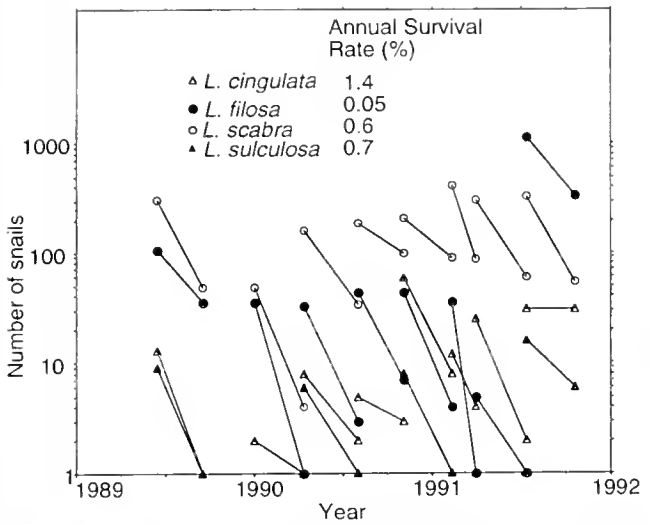

Figure 6. Numbers of snails painted at the beginning of an interval joined by straight lines to the numbers recaptured after a short interval, shown separately for the four species of mangrove snails, summed over all trees. The total numbers of individuals initially painted and the numbers of intervals providing data were 1,265 *Littoraria cingulata* (seven intervals), 2,488 *L. filosa* (eight intervals), 2,827 *L. scabra* (eight intervals), and 1,155 *L. sulculosa* (five intervals). The means and standard errors of [ln(painted) – ln(recaptured)]/[interval in years], which convert to annual survival rate as a proportion of one for the species in the same order, were −4.25 ± 1.12, −7.62 ± 1.29, −5.07 ± 0.75, and −5.02 ± 1.00.

by far at Mandu Mandu, in line with that site having the highest total abundance of snails during our entire study (Fig. 4). Furthermore, as for the total snails, the term for strip within site was the smallest, never more than 4%, emphasizing spatial consistency of adjacent strips within each site. For all species of recruits, the variance component for site × quarter term ranked second largest, ranging from 18 to 36%, indicating that the temporal pattern of recruitment differed among sites. As can be seen in Figure 5, the abundance of recruits of all species varied considerably and with different temporal patterns at the Mandu Mandu site. In summary, gains at an instant in time to the populations of rocky-shore snails were small in comparison with the total numbers, spatial variability was great, and temporal variability differed among species.

Survival and Growth of Littorines at Ningaloo Marine Park

The mark and recapture of painted snails provided quantitative estimates of rates of loss from the populations. We discovered that painted snails disappeared quickly from the mangrove trees, and our data consist of eight sets of painted snails observed between adjacent samplings (Fig. 6). Because the values are plotted on a logarithmic scale, the slopes of the lines connecting the numbers marked and recaptured for the groups of snails reflect the instantaneous rates of mortality, which we calculated using natural logarithms and then converted to estimates of annual rate of survival, whose averages are indicated in Figure 6. Clearly, the painted snails, which were mostly large snails rather than small recruits, disappeared at a very high rates so that the annual survival rates were low, with *L. cingulata* having the greatest survival rate at 1.4% and *L. filosa* the least at 0.05% per year. Besides being low, these estimates are also variable, with the instantaneous rates + 1 SE converting to 4.4, 0.2, 1.3, and 1.8% for *L. cingulata*, *L. filosa*, *L. scabra*, and *L. sulculosa*, respectively.

Figure 7 shows the survival of painted snails on the rocky shores. Like its congeners on mangroves, *L. undulata* had a low annual rate of survival of 3%. Similarly, our estimate of survival for the species lowest on the shore, *N. millegrana*, was low at 1%. We rarely recaptured any of these snails, except for those that we had painted as small recruits. On the other hand, *N. trochoides*, from high on the shore, was a survivor; its annual rate of survival was estimated as 24%, and we kept track of some individuals for 4 y before they disappeared. *N. australis* had an intermediate rate at 14%.

All our estimates of survival probably underestimate the true survival because the snails could lose their paint mark. Our census data during the period when we collected recruits provided a second estimate of survivorship, under the assumption that our collections stopped all input to the populations during that time, so that the populations lost snails only due to mortality. The analyses of the regression of ln(abundance) on date in years and the conversions to annual rate of survival in Table 2 show that the estimates were substantially higher than those calculated from the mark and recapture data for both the mangrove and rocky-shore snails but suffered from imprecision in the estimate of the slopes due to the small number of censuses conducted (all the rocky-shore species) and a lack of a distinctly linear decline (*L. cingulata*, *L. filosa*, and *L. undulata*). The estimate for *N. millegrana* is probably inappropriate for the reason stated earlier: This species never had any marked animals survive for more than a year. However, within habitats these estimates probably provide an indication of relative rates. Low survival rates have implications for other features of the life history of these snails, and the recaptured snails provided estimates of rate of growth because we could measure the size at which they were painted as well as size at recapture.

Table 3 shows a summary of the information on growth rates in terms of the fitted parameters for the von Bertalanffy growth equation. The thin-shelled mangrove littorines all had asymptotic sizes ($L\infty$) between 23 and 28 mm, considerably larger than the thicker-

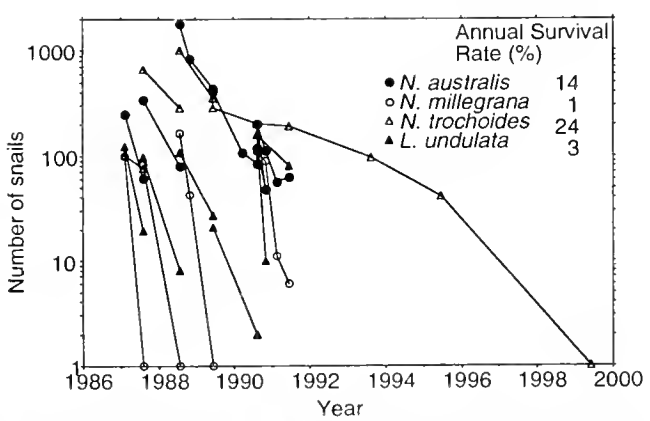

Figure 7. Numbers in groups of snails of the four species of rocky-shore littorines known to be painted at seven times and followed over at least one time interval at Mandu Mandu. Lines join the data for each group of snails. The total numbers of individuals initially painted and the numbers of intervals providing data were 3,174 *Nodilittorina australis* (seven intervals), 570 *N. millegrana* (six intervals), 2,452 *N. trochoides* (10 intervals), and 743 *Littoraria undulata* (seven intervals). The means and standard errors of [ln(painted) – ln(recaptured)]/[interval in years], which convert to annual survival rate as a proportion of one for the species in the same order, were −1.98 ± 0.26, −4.83 ± 1.15, −1.44 ± 0.80, and −3.36 ± 0.96.

TABLE 2.

Estimates of annual rate of survival derived from the slope of regression of natural logarithm of abundance of littorines (Y) on year (X) during the interval when recruits were removed regularly from the populations on trees A to E in Mangrove Bay and from the populations at Mandu Mandu.

Species	Number of censuses	Slope ± Standard Error (Probability, b = 0.0)	Coefficient of determination	Annual rate of survival (%)
Littoraria cingulata	4	−1.920 ± 1.773 (0.47)	0.75	14.7
Littoraria filosa	4	−1.561 ± 0.985 (0.25)	0.75	21.0
Littoraria scabra	4	−1.428 ± 0.578 (0.13)	0.73	24.0
Nodilittorina australis	3	−1.063 ± 0.030 (0.02)	0.99	20.1
Nodilittorina millegrana	3	−0.711 ± 0.109 (0.10)	0.98	49.1
Nodilittorina trochoides	3	−0.900 ± 0.160 (0.11)	0.97	40.7
Littoraria undulata	3	−0.173 ± 0.389 (0.73)	0.17	84.1

shelled rocky-shore snails with values between 10 and 18 mm. With the exception of *N. millegrana*, the rocky shore snails had lower growth rate coefficients (k) than the mangrove species. *L. filosa* and *N. millegrana* stood out as having substantially greater rates of growth than any of the other species.

Figure 8 provides a visual summary of the information about growth with plots of the average size at age predicted by the von Bertalanffy growth equations. The steepness of the rise of the curves reflects the magnitude of the growth coefficient (k), the elevation of the curves represents the asymptotic size ($L\infty$), and the curves for *L. filosa* and *N. millegrana* terminate at the time at which the predicted asymptotic length is reached (greater than 10 y for all the other species). There are three groups of growth curves in Figure 8: The three mangrove species grew fastest and reached the largest sizes, the high-shore *N. trochoides* grew at the slowest rate and reached only moderate size, and the other three rocky shore littorines grew at about the same intermediate rate but reached different asymptotic sizes. As an additional summary of the information on growth, Figure 8 shows the number of years at which the growth equation predicted that each species would reach half the asymptotic size, which is probably a biologically relevant indication of the demographic processes in these populations. By this measure, *L. filosa* and *N. millegrana* were the most ephemeral species because they were predicted to reach half size in less than 0.5 y. The other two mangrove species, *L. cingulata* and *L. scabra*, would reach that size in less than 1 y, and *L. undulata* and *N. australis* would take about 1.25 y. *N. trochoides* was predicted to take nearly 3 y to reach half size.

TABLE 3.

Estimates of the parameters of the von Bertalanffy growth equation* for the eight species of littorinid snails studied at Ningaloo Marine Park.

Habitat and species	Sample size	$L\infty \pm SE$	k ± SE
Mangroves (all trees)			
Littoraria cingulata	41	24.1 ± 3.85	0.72 ± 0.227
Littoraria filosa	340	23.9 ± 0.67	1.96 ± 0.183
Littoraria scabra	314	28.0 ± 0.91	0.89 ± 0.098
Rocky shore (Mandu Mandu)			
Nodilittorina australis	465	14.6 ± 0.11	0.65 ± 0.030
Nodilittorina millegrana	88	10.1 ± 0.61	1.30 ± 0.238
Nodilittorina trochoides	632	13.1 ± 0.27	0.23 ± 0.015
Littoraria undulata	36	18.4 ± 0.91	0.51 ± 0.096

* $L_t = L\infty (1 - e^{(-kt)})$, where $L\infty$ = asymptotic size, k = growth coefficient, and t = age in years.

Most of the records of growth for the mangrove littorines came from the groups marked in October 1991, but data from all intervals were included. The records for the rocky shore came from groups of snails initially marked in the winters of 1988 and 1989 and recaptured after one year, except or *Nodilittorina millegrana* for which we had recaptures in August after marking a cohort in November the previous year. Snails that survived for two or more intervals contributed growth information for each interval.

Covariation of Population and Life History Characteristics

The simultaneous investigations of eight species of littorines allow tests for strong patterns of covariation in the estimated demographic and life history parameters. The population characteristics available for seven of the species were the coefficients of variation for the abundances (measured on a logarithmic scale) of total snails and of recruits, and the sum of the variance components

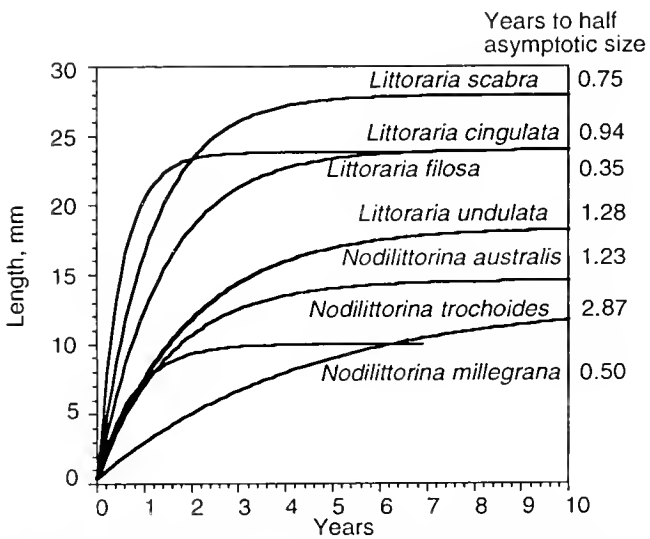

Figure 8. Predicted size-at-age from von Bertalanffy growth equations for three species of littorines from Mangrove Bay and four species from Mandu Mandu along with the age at which the snails are predicted to reach half their asymptotic size. The plots for *Littoraria filosa* and *Nodilittorina millegrana* end at the time at which the equation predicts that they would reach their asymptotic size; the others take longer than 10 y. The parameters of the von Bertalanffy equation, asymptotic size, $L\infty$, and growth coefficient (k) are shown in Table 3.

for temporal and temporal × site terms. The life history characteristics were the estimates of the growth rate constant and the time to half asymptotic size from fits to the von Bertalanffy growth equation and the two sets of estimated annual survival rate. Two patterns stood out, as shown in Figure 9.

The first pattern was a negative relationship between the coefficient of variation of the abundance of total snails and the mean of the abundance of recruits, with the position of the points for the rocky-shore species above and to the right of the mangrove species (Fig. 9a). On the rocky shore, *N. trochoides* and *N. australis* had higher recruitment and the least variable population of snails, *L. undulata* had the fewest recruits and the most variable population, and *N. millegrana* was intermediate. The pattern for the mangrove snails was less obvious, with *L. scabra* having more recruits and less variable populations than *L. filosa* and *L. cingulata*. These data address the issue of supply-side ecology by pointing to the contribution of abundant recruitment in stabilizing the populations.

The second pattern was a positive association between annual survival rate calculated from the recapture of painted snails and the predictions of years to half asymptotic size (Fig. 9b). There was a significant positive correlation involving all seven species, but it was unclear whether the important grouping of the points was associated with the genus of the snails or with the habitat in which they lived because *L. undulata* from the rocky shore was directly in line with its congeners from the mangroves.

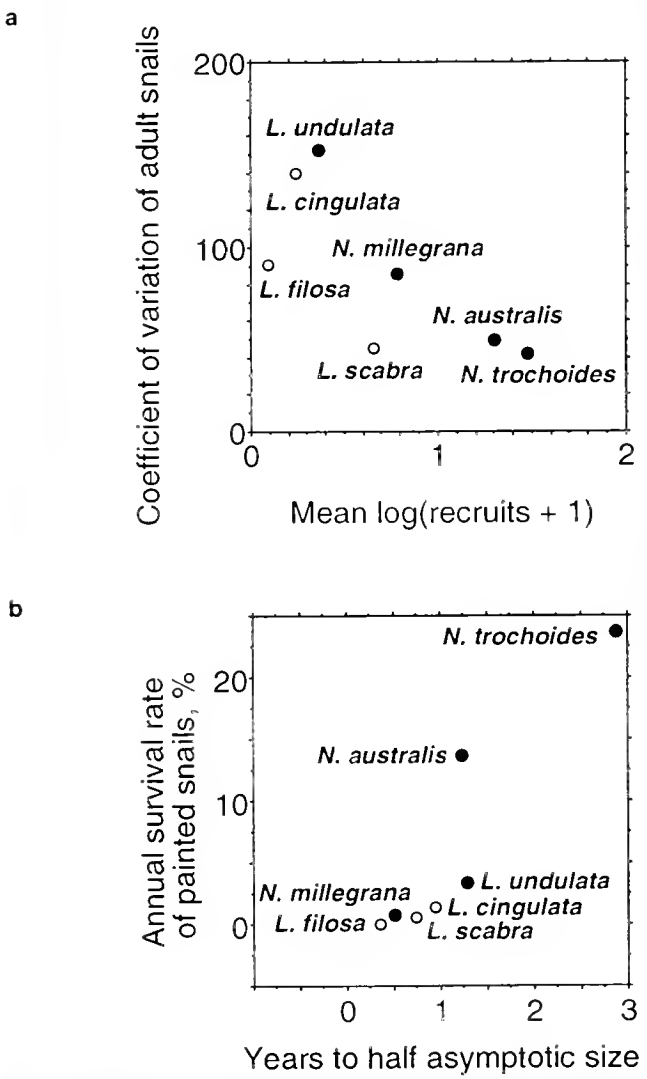

Figure 9. Covariation of demographic and life history characteristics of three species of mangrove littorines and four species of rocky shore littorines at Ningaloo Marine Park. (a) Overall, the coefficient of variation of adult snails and mean log (recruits + 1) had a significant negative correlation ($r = -0.73$), with the correlation coefficient for rocky-shore species higher ($r = -0.97$) and positioned farther to the right than for the mangrove species ($r = -0.70$). (b) Estimates of annual rate of survival of painted snails overall had a significant positive correlation ($r = 0.92$) with the years to half asymptotic size. The correlation coefficients for the three species of *Nodilittorina* and the four species of *Littoraria* were similar ($r = 0.95$ and $r = 0.94$, respectively) as were the correlation coefficients for the three mangrove species and the four rocky-shore species ($r = 0.95$ and $r = 0.91$, respectively).

DISCUSSION

This decade-long study of eight species of littorines at Ningaloo Reef revealed three important features of the population ecology of these species. The most conspicuous feature revealed was that, at the spatial and temporal scales used in this investigation and for the sets of species in the two habitats, the species' abundances varied largely independently, as indicated by the different patterns in the variance components (Fig. 2–5). Thus, even though all the species have planktonic larvae and our sites were spread over only 40 km of coastline, patterns of abundance of all snails and of recruits differed over space and time. There were, however, some conspicuous exceptions to this general feature in some components of the patterns. The abundances of *L. filosa* and *L. scabra* on the four groups of trees did vary in concert over time, but the patterns differed between these species. The differences in abundance of the rocky-shore littorines were dominated by differences among sites because of the consistently high numbers of all snails and of recruits at Mandu Mandu, where the four species also varied in concert. Finally, for total abundances, the variance component at the spatial scale of adjacent sampling units, represented by tree (group) and strip (site), was consistently the lowest for all species except for *L. scabra*, where it was the greatest. However, even these patterns are inconsistent across species, so, overall, patterns of spatial and temporal variability are unique for each species.

The second important feature involving abundances of these littorines was the relation between supply of recruits and the variability of the total abundances, especially for the rocky-shore species (Fig. 9a): The greater the number of recruits, the less variable was the number of snails. There is another aspect about the importance of the supply of recruits related to the source of the recruits. As can be seen in Figures 2 and 4, all the species except *L. scabra*, *N. australis*, and *N. trochoides* were absent from a group of trees or a site on at least one occasion. Because all the species recovered from being absent at a group or site, recruits must come from elsewhere, emphasizing the role of the planktonic larvae and the open nature of the populations. Furthermore, these absences of species from some sites at some times point out how misleading surveys at single sites and times could be about the distribution and abundance of these species. As a case in point, Reid (1986) specifically indicated that *Littoraria* spp. were not found at Mangrove Bay, presumably on the basis of surveys when the snails were scarce.

The third aspect about population ecology concerns the diversity of turnover rates exhibited by the eight species of littorines studied at Ningaloo Reef (Fig. 9b). The dynamics of populations of

L. filosa and *N. millegrana* operated much faster than other species, with fast rates of growth combined with low rates of survival suggesting an annual life cycle, as has been interpreted for other littorines (e.g., Underwood & McFadyen 1983 for *L. acutispira* and Williams 1992 for *L. mariae*). *N. trochoides* was at the other extreme, with high survival and a slow rate of growth and probably being long-lived like *L. neritoides* (Hughes & Roberts 1981). On average, the mangrove species were more ephemeral than the rocky-shore species, but both groups vary considerably, and it is impossible to determine from our small sample and the ambiguous position of *L. undulata* whether the patterns in Figure 9b are driven by habitat or generic relationship. To our knowledge, this is the first comparative study of demography in species of *Littoraria* and *Nodilittorina*. The variability and the apparent patterns highlight the potential of these snails for testing general ideas about life-history evolution.

PREDATION BY THE PILE PERCH, *RHACOCHILUS VACCA*, ON AGGREGATIONS OF THE GASTROPOD *LITTORINA SITKANA*

ELIZABETH G. BOULDING,* DEBORAH PAKES, AND STEPHANIE KAMEL
Department of Zoology, University of Guelph, Guelph, Ontario N1G 2W1, Canada

ABSTRACT The pile perch, *Rhacochilus vacca* (Embiotocidae), is abundant on the Pacific Coast of North America and is known to crush hard-shelled prey with its heavy pharyngeal teeth. We investigated whether pile perch predation has the potential to limit or regulate populations of *Littorina sitkana*, a direct-developing gastropod found on wave-sheltered shores near Bamfield, British Columbia, Canada. Laboratory experiments showed that pile perch required an average of only 19.2 sec (SE = 5.61; $n = 20$) to crush and swallow a large *L. sitkana*, which resulted in consumption rates averaging 33.3 (SE = 6.27; $n = 4$) large snails per day. The snails had no size refuge from predation by adult fish because even small fish (fork length 21 cm) could crush the largest *L. sitkana* present on the shore (>11 mm shell width). Indeed, some fish showed a significant preference for large snails (shell width >6.3 mm) over small snails (3.35 mm < shell width < 4.0 mm). Our 1998 observations with SCUBA during daytime high tides showed that the density of pile perch foraging in the intertidal averaged 0.119 (SE = 0.0205; $n = 20$) individuals per square meter (estimated fork lengths 5–40 cm). However, the intertidal distribution of pile perch that were actually consuming prey was highly aggregated. In the field, we investigated whether predation by this fish on snails deployed onto boulders was density dependent. The fish swam parallel to the shore and located and consumed 40% of the patches of *L. sitkana* that we deployed ($n = 70$) within 50 min. This foraging behavior resulted in density-dependent predation on the deployed snails in only one of the three tidal cycles (or 2 of the 12 days) of our experiment. We offer several proximate reasons for the low frequency of density-dependent predation found in this study and conclude that the pile perch may not be an important regulating factor for *L. sitkana* populations at this site at the present time. However, the very high predation rates we observed suggest that this predatory fish is an important limiting factor at this site.

KEY WORDS: aggregative response, limiting factor, population regulation

INTRODUCTION

The factors that determine the distribution and abundance of marine invertebrates are still not well understood. Predation is known to be important in limiting the abundance of littorinid gastropods on rocky shores. Paine (1994) reviewed examples where predators had been excluded from rocky shores and concluded that such exclusions usually resulted in dramatic increases in the abundance of the competitive dominant. Many of the classic exclusion experiments he reviewed have involved slow-moving predators, such as gastropods or starfish. However, slow-moving predators are unable to move rapidly to high-density aggregations of their prey and are generally less tolerant to emersion than their prey (Newell 1970). As a result, they usually have a very local effect at the lower end of the intertidal distribution of their prey. In contrast, highly mobile predators, such as crabs and fish, can forage throughout the intertidal during a single high tide period and have been observed to feed more heavily on high-density aggregations of their prey (Boulding & Hay 1984, Behrens Yamada & Boulding 1996). Sinclair (1989) argues that only density-dependent factors can provide the negative feedback that can regulate a population at equilibrium. Consequently, highly mobile predators may be disproportionately important as regulating factors on rocky intertidal shores.

Two highly mobile predators, crabs and fish, can prey very heavily on littorinid gastropods on wave-sheltered shores of the northeastern Pacific, and it is not clear which predator type is more important. McCormack (1982) deployed *Littorina sitkana* into fenced areas of the intertidal and observed predation rates of up to 54% per daytime high tide period, which she attributed entirely to predation by pile perch (*Rhacochilus vacca*). Behrens Yamada and Boulding (1996) tethered *L. sitkana* in the intertidal zone and found predation rates of up to 77% per high tide period. They recovered diagnostic shell fragments that had been peeled by crabs from 40% of the dead snails of shell length 15–17.5 mm. Boulding et al. (1999) found predation rates on tethered *L. sitkana* to be up to 25% per high tide period and used shell fragments to attribute at least 52% of the predation of their largest size class to predation by crabs. The daily rates of predation reported above are too high for any *L. sitkana* population to sustain given their known reproductive rates (Behrens Yamada 1989). We hypothesize that these high predation rates represent a strong density-dependent response to local high-density patches of prey and present experiments here to test our hypothesis.

Foraging excursions into the intertidal during high tide have been well documented for large subtidal crabs such as *Cancer productus* (Boulding & Hay 1984, Robles et al. 1989, Behrens Yamada & Boulding 1996, Boulding et al. 1999). There is experimental evidence that predation by this crab species can be density dependent (Boulding & Hay 1984).

However, much less is known about the foraging behavior of the pile perch other than its extreme morphological specializations for crushing hard-shelled prey (Brett 1979). One of the major components consistently found in stomach analyses of pile perch are gastropod molluscs (Ellison et al. 1979, Haldorson & Moser 1979, Hueckel & Stayton 1982, Laur & Ebeling 1983, Stouder 1987). The only other surf perch that is common in the intertidal zone on the west coast of Vancouver Island and is known to eat gastropods is the striped perch (*Embiotoca lateralis*) (Lamb & Edgell 1986, E.G. Boulding Pers. Comm.). Striped perch stomachs sometimes contain gastropod mollusks, but soft bodied invertebrates such as amphipods, bryozoans, and isopods are much more prevalent (Haldorson & Moser 1979). The different feeding preferences of the two species are correlated with their mouth size and structure. The pile perch has extremely large pharyngeal plates, heavy blunt (pavement-like) pharyngeal teeth, and well-developed associated musculature for specialization in crushing and grinding (DeMartini 1969). The striped perch, however, has only moder-

*Corresponding author. E-mail: boulding@uoguelph.ca

ately sized pharyngeal plates; smaller, more pointed pharyngeal teeth; and moderately developed musculature and is specialized for feeding on large whole prey (DeMartini 1969). For these reasons, we decided to focus on determining whether pile perch predation on patches of *L. sitkana* deployed onto a rocky intertidal shore was density dependent.

MATERIALS AND METHODS

Study Area

Our experimental site was located on a wave-sheltered boulder shore in front of Bamfield Marine Station (48°50′, 125°08′) in Barkley Sound, Vancouver Island, British Columbia, Canada. We chose the site because it was one of the sites ("Pebble Beach A," hereafter Pebble Beach) used by McCormack (1982) in her study of the role of pile perch in maintaining shore-level size gradients in *L. sitkana* populations.

Laboratory Feeding Experiments

Our laboratory feeding experiments were conducted in round fiberglass tanks at Bamfield Marine Station. The experimental tanks were either 1.22 or 1.83 m in diameter and were filled with free-flowing sea water to a depth of 0.914 m. The tanks were covered with plywood but were left open along a 20-mm crack to allow for low levels of light. The flow rate of seawater into the tanks was at least 1 l/s, and the water had a temperature of 10 ± 1°C and a salinity of 31‰.

The pile perch were collected by fishing with a hook baited with a whole mussel (*Mytilus trossulus*). Upon landing, the hook was carefully removed with pliers, and the fish was placed in a bucket of sea water and rapidly transported to 2.44-m diameter round holding tanks. The fish were then held for at least a week and maintained on a diet of *M. trossulus*. The total length of the fish collected ranged from 275–330 mm.

L. sitkana were collected from Seppings Island near Bamfield Marine Station. The large size-class of snails was also collected from nearby Second Beach. They were held in perforated containers in free-flowing sea water until used in the experiments. The size of the minimum diameter (shell width) of the snails was determined by passing them through a series of brass soil test sieves stacked so that the mesh size decreased from the top sieve to the bottom sieve.

Three different feeding experiments were conducted using one fish in each experimental tank. In the first experiment (Consumption Amount) we offered each of four pile perch 100 extra-large (>6.3 mm shell width) *L. sitkana* placed at the bottom of the tank. After 24 h we recorded the number of live snails above, at, and below the water line and then removed the live snails and the shell fragments from each tank. This experiment was continued for nine replicate days. We chose not to use repeated measures analysis of variance (ANOVA) because our primary objective was to compare the consumption rates of the different fish rather than trends over time. Instead, we used a one-way ANOVA with FISH as the factor and then used Bonferroni pairwise comparisons to determine whether some individual fish ate more than others. We used version 5 of the statistical package SYSTAT for this and all other statistical analyses (SYSTAT 1992).

In the second experiment (Size-Selection) we offered each of four pile perch 100 extra-large and 100 small (3.35 mm < shell width < 4.0 mm) *L. sitkana*. After 24 h we recorded the number of live snails of each size-class above, at, and below the water line. We then removed the live snails and the shell fragments from each tank. This experiment was conducted for 6 days. To analyze the data we used three-way ANOVA with DAY, FISH, and SIZE as the factors and included only the interaction we thought most important, FISH × SIZE, in our model. One fish did not eat and was excluded from further analysis.

In the third experiment (Consumption Rate) we opened the crack in the plywood cover to 10 cm and offered each of four pile perch 20 large *L. sitkana* (4.75 mm > shell width < 6.3 mm). We then used a stopwatch to record the time it took the fish to crush each snail. We noted that only certain fish would feed while being observed.

Field Transects

In 1998 we deployed two 50-m transect lines at Pebble Beach (below the *Fucus* zone) parallel to the depth contours at 0.8 m and 1.1 m above 0.0 datum (Canadian Hydrographic Services). The transects were surveyed for pile perch and striped perch densities. Counts were done using SCUBA during high tides of 3.0 m or greater such that the upper transect (1.1 m) was in at least 1.9 m of water. Two observers swam along the transect line, one on each side, for about 15 min recording fish densities and size classes within 2 m of their side of the line. Fish size-classes were divided into 5-cm intervals from a minimum length of 5 cm to a maximum length of 40 cm. A total of five surveys were done in July 1998. We did four similar transect surveys between June 28 and July 1, 1999, except that these transect lines were at 0.0 m and 1.3 m above 0.0 datum (Canadian Hydrographic Services). In 1999, we tested how good the divers were at estimating the total length of the fish by placing models of different sizes of fish underwater at distances from 2–6 m from each diver and asking her to estimate its total length.

We estimated the abundance and mean size of mollusc prey at Pebble Beach by counting and measuring the molluscs in five 10-cm × 10-cm quadrats sampled at random along a tape measure placed on the beach, parallel to the water's edge, at low tide. The sampling was repeated at 1.5 m, 2.2 m, 2.8 m, and 3.2 m above 0.0 m datum. Because only one *L. sitkana* was found in the quadrats, an additional search was done to find *L. sitkana* by walking along the entire beach at low tide and turning over rocks for a total of 2 h. The abundances were then compared with estimates of *L. sitkana* density done by McCormack at the same site in 1981.

Field Experiments

In 1999 we used SCUBA to deploy three high-density and three low-density replicate patches of snails each day at high tide for a total of 12 days. A container with either a high-density patch (n = 50 snails) or a low-density patch of *L. sitkana* (n = 5 snails) was chosen at random from the mesh bag carried by the divers. The divers opened the container, and the snails were placed on boulders along the 1.3-m depth transect line. We chose boulders that were flat on top, about 0.3–0.6 m in diameter and 0.3–0.5 m high, and cleared them of macroalgae. This clearing was done to reduce variance among replicates caused by the snails hiding more effec-

tively on some rocks than on others. After 40–50 min the divers returned to the boulder, collected all the live snails and shell fragments from the boulder and surrounding area, and placed them in labeled containers.

All shell fragments we collected from our experimental boulders could be attributed to predation by fish and not by crabs. In our laboratory experiments we noted that pile perch preying on snails immediately spat out small broken pieces of shell body whorl. However, they swallowed the columella and later excreted it in a mucus-coated pellet onto the tank floor. All shell fragments found in our field experiment were small broken pieces, and no columellas were seen. We also did not see pelleted fragments of columellas, probably because fish retreated to the subtidal before defecating. This is distinct from shell fragments formed as a result of predation by crabs, which typically have either an intact columella with a spiral gouge up the body whorl or broken pieces of columella (Zipser & Vermeij 1978, Lawton & Hughes 1985, Behrens Yamada & Boulding 1996).

Upon returning to the laboratory we counted the number of replicate patches in which we found shell fragments. We also counted the percentage of live snails that we had deployed that were recovered. The data were analyzed with contingency table analysis and with ANOVA.

Contingency Table Analysis

The different dates of the experiment were categorized into three separate spring (or large) tide series: A, B, and C. Tide A refers to dives from June 28 to July 1, Tide B is from July 12 to July 14, and Tide C is from July 29 to August 3, 1999. We assumed predation by pile perch when we recovered shell fragments on or near the rocks where snails were deployed. First, tidal series A–C were compared with each other in a pairwise fashion to test for differences in the mean percentage of the deployed patches that experienced predation using Fisher's Exact Test. Tidal series B and C showed no differences in mean percentage predation per day; they were therefore lumped together. Differences in mean percentage predation between high- and low-density patches were then compared within the two new groups using Fisher's Exact Test.

ANOVA

We compared the mean percentage of snails we recovered in the high patches vs. the low patches across the 12 days using a factorial ANOVA model with date and treatment as the factors. We then used Fisher's Least Significant Difference test to determine which pairs of means were significantly different.

RESULTS

Laboratory Experiments

The four pile perch in the consumption experiment ate an average of 33.3 ± 6.3 snails per day (mean ± SE). The largest fish (total length = 330 mm) ate significantly more snails ($P < 0.006$) than one of the smallest fish (total length = 280 mm). We observed that when the *L. sitkana* were placed in the bottom of the tanks they eventually crawled up to or above the water line, which made them inaccessible to the fish. We therefore reanalyzed the data considering only the consumption rate of the snails found at or below the water line but got very similar patterns. The fish ate

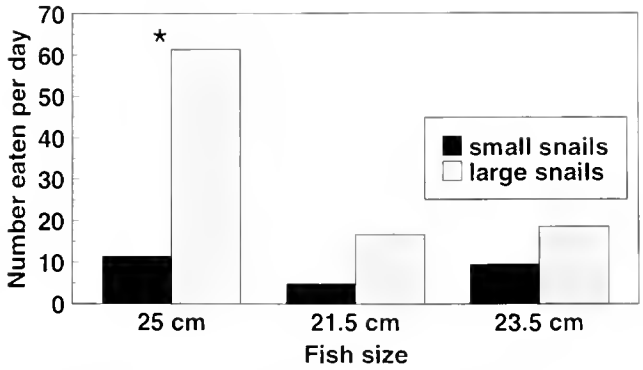

Figure 1. Size-selection for larger snails (*Littorina sitkana*) in the laboratory consumption experiment. *indicates a fish which ate significantly more large snails (Bonferroni pairwise comparisons, $P < 0.05$).

32–61% of the snails available with the largest fish again eating significantly more than the smallest fish ($P = 0.033$).

Only the largest of the three remaining pile perch (total length = 330 mm) in the size-selection experiment showed a significant preference for the extra-large size-class of *L. sitkana* over the smallest size-class (Fig. 1). There was a significant interaction between FISH and SIZE ($P < 0.001$) but no significant effect of DATE ($P = 0.319$).

The laboratory consumption experiment verified that the pile perch were very efficient predators on the snails, but only one fish would feed while being watched. One 250-mm fish required only 42.9 ± 8.02 sec (mean ± SE, $n = 19$) to consume each large *L. sitkana* (shell length 10 mm). The same fish became even more efficient at eating the snails by the next day and required only 19.2 ± 5.61 sec (mean ± SE; $n = 20$) to consume each snail.

Field Transects

The average density of pile perch in the intertidal at high tide was moderately low and was concentrated in the middle intertidal zone. In 1998, the average density of pile perch in the 0.8- and 1.1-m transects combined was an order of magnitude higher than the average density of striped perch (Table 1). In 1999, the densities of pile perch and striped perch in the 1.3-m transect were similar to those observed in the 0.8- and 1.1-m transects in the previous year (Table 1). However, in 1999 we also surveyed a 0.0-m transect where we observed no striped or pile perch (Table

TABLE 1.

Density of pile perch and striped perch in 1998 and 1999 in transects at Pebble Beach near Bamfield Marine Station.

Year	Species	Mean density	SE	n[d]
1998[a]	Pile perch	0.119/m^2	0.0205	20
	Striped perch	0.0205/m^2	0.0055	20
1999[b,c]	Pile perch	0.124/m^2	0.0221	16
	Striped perch	0.0275/m^2	0.00818	16

[a] Densities are taken from an average of 0.8 m and 1.1 m above 0.0 datum transects.

[b] Densities are taken from 1.3 m above 0.0 datum transect.

[c] No fish were seen at 0.0 m; $n = 6$.

[d] n is number of transects surveyed.

1). Most of the fish that we observed in both years were small. In 1998 the average length of the pile perch was 12.0 mm, and the average length of the striped perch was 11.2 mm (Table 2). In 1999, the average length was slightly larger for both species, with the pile perch averaging 15.2 mm and the striped perch averaging 13.5 mm (Table 2). In 1998 most fish were small, but some pile perch were more than 30 cm in length (Fig. 2). We found that experienced divers were good at estimating the total length of model fish. All three divers were able to place the models into the correct 5-cm size-class 95% of the time.

Our quadrat sampling of Pebble Beach estimated that the current densities of *L. sitkana* and other potential prey species for the pile perch were very low. The most common prey species found were the gastropods *L. scutulata* and *Tegula funebralis*, and even these were not abundant (Table 3). *L. sitkana* was especially rare, with only one found in the entire quadrat survey and only three more found after walking the entire beach. The density of mussels (*M. trossulus*) was very low, but the abundance of barnacles (*Balanus glandula*) was high.

Field Experiments

Contingency Table Analysis

A total of 40% of all the patches deployed in this experiment ($n = 70$) were found by fish within 50 min. We found that the number of patches where we found shell fragments (i.e., predation) was significantly higher in the second and third tidal series than the first (A vs. B: $P < 0.004$, df = 1, $n = 41$; A vs. C: $P < 0.036$, df = 1, $n = 52$). The percentage of patches in each tidal series where we found shell fragments is shown in Figure 3. The second and third tidal series were not significantly different from each other in the number of patches that experienced predation and were thus lumped together for analysis of treatment effects (B vs. C, $P = 0.37$, df = 1, $n = 47$). In the first tidal cycle, significantly more of the high-density treatments experienced predation (Table 4). In the second and third tidal series, there was no difference in the percentage of the patches that experienced predation between the high- and the low-density treatments (Table 4). The mean percentage predation in the low- and high-density treatments is shown in Figure 3 for each tidal series. In all patches where shell fragments were found, an average of 81 ± 0.06% ($n = 26$) of the snails deployed were eaten.

ANOVA

A significant DATE × TREATMENT interaction was found for the percentage of recovered snails (Table 5); therefore, we present only the interaction means (Fig. 4). We recovered a significantly lower proportion of snails from the high-density patches than from the low-density patches on 2 of the 12 days of the experiment (June 28 and July 13). We observed an inverse density-dependent trend on 3 days, but these were not significant (Fig. 4).

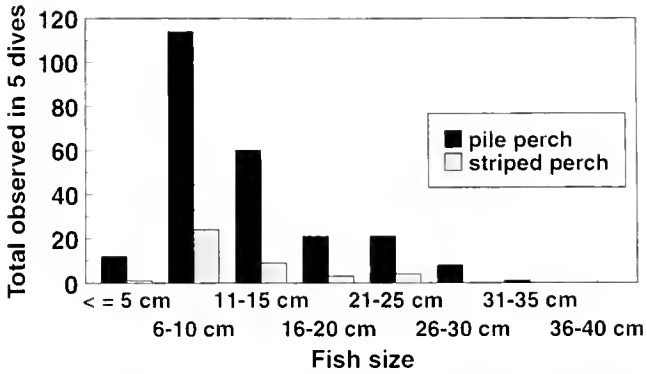

Figure 2. Size-distribution of the pile perch, *Rhacochilus vacca*, and the striped perch, *Embiotoca lateralis*, seen in intertidal transects in 1998.

The divers made some additional observations on foraging pile perch. In 1998, divers at Pebble Beach watched two 35-cm pile perch consume a patch of deployed snails and noted that they required only 9 min to consume a total of 17 snails. As previously mentioned, in 1999, divers left the patches for at least half an hour after they had deployed the snails. However, by the third spring tidal series they noticed that some fish began to circle the divers before all the snails were deployed. Although divers were not present during the entire time that the snail patches were deployed, any predation that was observed was always by pile perch.

DISCUSSION

This study shows that pile perch were the major consumers of the large *L. sitkana* we deployed in the Pebble Beach intertidal during diurnal high tides. Striped perch were much less common in the field transects at Pebble Beach, and we did not observe striped perch eating the snails we deployed. The pile perch has previously been implicated as an important predator of littorinid gastropods on wave-sheltered shores of the Northeastern Pacific (McCormack 1982, Boulding et al. 1999). However, there has been some question about its importance because at some sites predation rates by

Percentage of snail patches deployed where shell fragments were found at Pebble Beach in high-density and low-density treatments for tidal series A (June 28 through July 1, 1999), B (July 12 through July 14, 1999), and C (July 28 through August 3, 1999). *Significant differences between densities (Fisher's Least Significant Difference test, $P < 0.05$).

pile perch have been estimated to be close to zero (Behrens Yamada & Boulding 1996). In our experiment the pile perch found 40% of the deployed patches of snails. Within the patches found by the fish, the consumption rate averaged 81%. This suggests that pile perch have the potential to severely limit the size of *L. sitkana* populations. We doubt that predation rates on the natural snail population on Pebble Beach are nearly so high because the population is currently at a very low density. However, natural populations of *L. sitkana* do occur at higher densities at other locations (McCormack 1982), and pile perch predation rates on these populations may be high.

Adult pile perch exhibited a very high foraging efficiency when feeding on large *L. sitkana*. The pile perch consumed snails at a very high rate (19.1 sec per snail). The largest fish showed a size preference for large snails, which makes it unlikely that certain size-classes of *L. sitkana* have a size refuge from pile perch. In addition, large pile perch were moderately abundant in the intertidal zone at high tide at Pebble Beach and reached fish densities of 0.119/m^2. This is an order of magnitude higher than the only previously reported densities for pile perch of 0.0039–0.0109/m^2 in kelp beds off southern California (Ebeling et al. 1980). These data suggest that the pile perch could be an important limiting factor for the population of *L. sitkana* at this site.

TABLE 4.

Number of high- and of low-density patches of *Littorina sitkana* deployed at Pebble Beach in 1999 that were recovered with and without shell fragments resulting from predation by pile perch.

[a] Percentage of live snails (*Littorina sitkana*) recovered after exposure to predation during one high tide period. Data were transformed with an angular transform before analysis.

When a pile perch found a patch of deployed snails in our field experiment, it ate the majority of the snails. Density-dependent predation can result from a predator finding high-density patches of prey more often or from the predator spending more time in high-density patches once they are found (Krebs & Davies 1991). Consumption rates were high in all patches that were found suggesting that the fish were not spending more time in high-density patches than in low-density patches. Therefore, any density-dependent predation we observed probably resulted from the fish finding high-density patches more easily than low-density patches. No work has been done specifically on the searching behavior of the pile perch, but they are known to be visual predators that feed during the day (Ellison et al. 1979). Many other benthivorous fishes that feed diurnally are know to use vision almost exclusively to find prey (Keenleyside 1979).

Our analysis by tidal series found significant density-dependent predation in the first tidal series (A) but not the second (B) and third (C). We doubt the lack of significance in tidal series B and C is due to low statistical power because sample sizes were smallest in tidal series A. Furthermore, we also observed a low frequency of density-dependent predation when we analyzed our experiment with ANOVA, detecting it on only 2 of the 12 days.

There may be several reasons why our study did not frequently detect density-dependant predation of *L. sitkana* by pile perch. In tidal series C, the divers noticed several large pile perch following them that consumed the snails as soon as they were deployed.

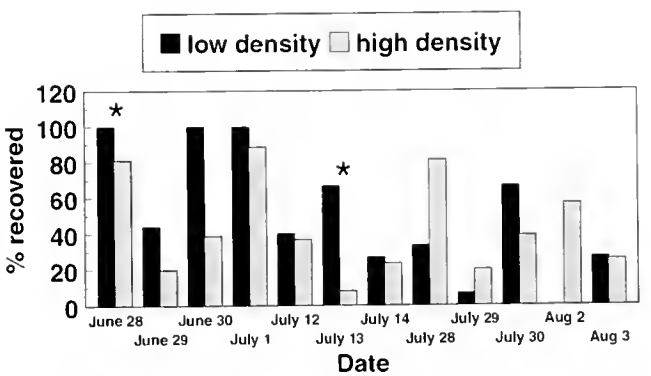

Figure 4. Mean percentage of snails (*Littorina sitkana*) recovered from the low- and high-density treatments on six different sampling dates. *Dates on which a significantly higher percentage of snails was recovered from the low-density treatment (Fisher's Least Significant Difference test, $P < 0.05$).

This suggests that the fish had become habituated to the divers and used their presence as a cue to find the patches of snails. This behavior may have made it difficult to detect density-dependent predation.

Another explanation for the low frequency of density-dependent predation is that the high consumption rate of snails by pile perch in both the high- and the low-density treatments made it difficult to detect subtle density-dependent predation. Our ability to detect density dependence was further reduced by our inability to distinguish snails that had been consumed from those that had simply migrated away from the top of the boulder. A single missing snail would affect the percentage recovered in the low-density treatment much more strongly than in the high-density treatment. For example, two snails migrating from the low density-treatment where a total of only five were deployed would result in a 60% recovery of snails, whereas two snails migrating from the high-density treatment would result in a 96% recovery.

In addition, the low-density treatments may have been in fact high density when compared with the present ambient density of possible prey species at this site. Almost no *L. sitkana* were found in our quadrats at Pebble Beach. Two other gastropod species were present at Pebble Beach, *L. scutulata* and *Tegula funebralis*, but neither are preferred prey of pile perch. Adult *Tegula* are rejected by pile perch (McCormack 1981), whereas the *L. scutulata* present on this beach averaged only 5.21 mm in shell length and are likely too small to be profitable. We suspect that the intense predation by pile perch at Pebble Beach keeps the densities of their preferred prey very low. Indeed, the low densities of potential prey items found there in 1999 cause us to question why the fish are venturing in the intertidal at all. The pile perch may be feeding on the barnacles there as was observed by our divers in 1998. Barnacles were reported to make up 56–75% of the stomach contents of large pile perch foraging on an artificial reef off the Washington coast (Hueckel & Stayton 1982).

Given the high predation rates we observed, we find it highly unlikely that any of the deployed snails would have survived if left out for another hour. The ambient density of prey may have been exceptionally low at Pebble Beach in 1999 that an unusually high proportion of the deployed snails were found and eaten. McCormack (1981) found much higher densities of *L. sitkana* at Pebble Beach in 1980 (10 snails/m^2 at 1.5 m tidal height and 970 snails/m^2 at 2.2 m in 1980) than we did (Table 3). We hypothesize that, rather than being regulated at an equilibrium density, there may be large fluctuations over time in the density of this *L. sitkana* population.

This study did not find predation by the pile perch on deployed patches of littorinid prey to be consistently density dependent. Consequently, we lack strong evidence that this predator has the potential to be an important regulating factor for the *L. sitkana* population at this site. Nevertheless, its high success rate at locating patches, its high foraging efficiency, and the high mortality rates we observed for the deployed prey suggests that the pile perch is an important limiting factor for the snail population at this site.

ACKNOWLEDGMENTS

We thank M. Gray, T. Hay, and T. Lundrigan for their suggestions for improving the manuscript, T. Hay and E.N. Hay for collecting fish, L. Kusumo for technical assistance, S. Servant and S. Zaklan for SCUBA observations, the Director and staff of Bamfield Marine Station for field support, and the Huu-ay-aht First Nation for access to our study sites. RADULAR MYOGLOBIN AS A MOLECULAR MARKER IN LITTORINID SYSTEMATICS (CAENOGASTROPODA)

CARLOS BRITO,[1] PAULINHA LOURENÇO,[1] ROBERTO MEDEIROS,[1] JOSE F. REBELO,[1] HANS DE WOLF,[2] KURT JORDAENS,[2] AND THIERRY BACKELJAU[2,3,*]

[1]Department of Biology, University of the Azores, Rua da Mãe de Deus 58, Apartado 1422, P-9502 Ponta Delgada, Azores, Portugal; [2]Department of Biology, University of Antwerp (RUCA), Groenenborgerlaan 171, B-2020 Antwerp, Belgium; [3]Royal Belgian Institute of Natural Sciences, Vautierstraat 29, B-1000 Brussels, Belgium

ABSTRACT Radular myoglobin (Mb) was investigated in 288 specimens of 10 littorinid species using vertical polyacrylamide gel electrophoresis (PAGE) and isoelectric focusing (IEF). Within the genus *Littorina* the two most basal species, *L. striata* and *L. keenae*, have Mb patterns that correspond to those of the genera *Littoraria* and *Nodilittorina*, while the sibling species *L. scutulata* and *L. plena* have identical Mb profiles that consistently differ from those of *L. littorea*, *L. saxatilis*, *L. compressa* and *L. arcana*. In contrast to previous claims, Mb does not consistently separate the sibling rough periwinkles *Littorina saxatilis* and *L. arcana*. These data suggest (1) that the *Nodilittorina/Littoraria* Mb profile in *L. striata* is not unique within the genus *Littorina* and therefore does not refute the assignment of *L. striata* to this genus, and (2) that *L. scutulata* and *L. plena* occupy a separate position compared to the other species of the subgenus *Littorina*. This latter result supports the suggestion that *L. scutulata* and *L. plena* may constitute a separate subgeneric taxon. Finally, the IEF Mb profiles of *Nodilittorina hawaiiensis* and *Cenchritis muricatus* were nearly identical to the *Nodilittorina/Littoraria* Mb pattern. Yet, PAGE of Mb in *Cenchritis muricatus* suggests a tentative Mendelian polymorphism. It is concluded that littorinid Mb may not be a useful marker to distinguish closely related species, but rather provides information on 'higher level' systematics.

KEY WORDS: Caenogastropoda, isoelectric focusing, Littorinidae, myoglobin, protein electrophoresis, systematics

INTRODUCTION

With only two published studies prior to 1998, radular myoglobin (Mb) has not been widely used in littorinid systematics and population genetics (Wium-Andersen 1970, Jones 1972). This is not unexpected since the genetic background of Mb variation in periwinkles remains obscure and controversial (Olabarria et al. 1998). Nevertheless, it has been shown that simple protein electrophoretic surveys of Mb can provide useful data for littorinid systematics and population genetic analyses (De Wolf et al. 1998, Medeiros et al. 1998, Olabarria et al. 1998). In this context, Medeiros et al. (1998) observed that within the genus *Littorina* there was considerable intra- and interspecific Mb differentiation. This allowed, for example, to separate the sibling rough periwinkles *Littorina (Neritrema) saxatilis* and *L. (N.) arcana*. In contrast, the Mb patterns of two *Littoraria* species and three *Nodilittorina* species were almost, if not completely, identical. Interestingly, the Mb profile of *L. striata* was similar to that of *Littoraria* spp. and *Nodilittorina* spp., but differed conspicuously from that of *Littorina* spp. This latter result could be interpreted in two ways: either *L. striata* is not a *Littorina* or the Mb profile of *L. striata* represents a plesiomorphic condition within *Littorina*.

The present contribution is a follow-up of the work by Medeiros et al. (1998). In particular, we will: (1) test the reliability of Mb as species marker to differentiate between *L. saxatilis* and *L. arcana*, (2) compare the Mb profile of *L. striata* with those of three other basal *Littorina* species, which are supposed to represent its closest relatives (*L. keenae*, *L. scutulata* and *L. plena*) (Reid 1990, Reid 1996, Reid et al. 1996), and (3) evaluate the electrophoretic Mb monomorphism in *Littoraria* and *Nodilittorina* (and related genera) by resolving Mb patterns in two additional species (*Nodilittorina hawaiiensis* and *Cenchritis muricatus*).

Throughout this article we will follow the taxonomy and nomenclature proposed by Reid (1989, 1996). We will use the abbreviation '*L.*' for the name *Littorina*, whereas the name *Littoraria* will be written in full.

MATERIALS AND METHODS

Electrophoretic profiles of radular Mb (and other structural proteins in the radular muscle) were surveyed in 288 periwinkles representing 10 species (Table 1). After collection specimens were transported alive or in liquid nitrogen to the laboratory, where they were stored at −80°C. Sample preparation was as described by Medeiros et al. (1998) and adapted in order to reduce possible artificial Mb variation caused by oxidative denaturation (e.g. Di Iorio 1981, Righetti 1983). Therefore individual radular tissue homogenates were prepared by thawing frozen snails, crushing their shells and dissecting the radular muscle in cold distilled water. The radular muscle was then blotted on filter paper and homogenized in a 0.1% KCN (w/v) in 20% (v/v) glycerol solution, in a ratio of 20µl solution per mg tissue. KCN converts Mb to cyanometmyoglobin, which is more stable and prevents denaturation to hemichromes (Atassi 1964, Di Iorio 1981). Crude homogenates were subsequently centrifuged for 30 min at 27200 × *g* (15000 r.p.m.) at 4°C. The resulting supernates were stored at −80°C until used for electrophoresis.

Vertical polyacrylamide gel electrophoresis (PAGE) was performed in 80 × 80 × 0.75 mm gels ('Mini Protean II' apparatus of Biorad) with a gel strength of 7% and using a discontinuous buffer system with Tris/HCl pH 9.0 as gel buffer and Tris/Glycine pH 9.0 as tray buffer (Backeljau 1989). Otherwise, PAGE procedures and conditions were as described by Medeiros et al. (1998). The protocols of these authors were also followed to perform horizontal isoelectric focusing (IEF) in pH gradients 3–9 and 4–6.5. PAGE and IEF gels were stained for general proteins (including Mb) with Coomassie Brilliant Blue and specifically for Mb with a benzidine recipe (Medeiros et al. 1998).

TABLE 1.

List of littorinid species and collection sites screened for Mb variation

Species	Locality	*N*
Melarhaphe neritoides (Linnaeus, 1758)	Pico, Azores	10
Cenchritis muricatus (Linnaeus, 1758)	Isla Margarita, Venezuela	15
Nodilittorina hawaiiensis Rosewater & Kadolsky, 1981	Hawaii	15
Littorina (Littorina) striata King & Broderip, 1832	São Miguel, Azores	15
	Pico, Azores	15
	Terceira, Azores	15
	Madeira	4
Littorina (Planilittorina) keenae Rosewater, 1978	San Simeon, CA, USA	15
	Leo Carrillo Beach, CA, USA	15
	Morro Bay, CA, USA	15
Littorina (Littorina) plena Gould, 1849	Leo Carrillo Beach, CA, USA	15
	Morro Bay, CA, USA	15
Littorina (Littorina) scutulata Gould, 1849	Morro Bay, CA, USA	4
Littorina (Neritrema) compressa Jeffreys, 1865	Port Bhéal an Duin, Ireland	15
	Trébeurden, France	15
Littorina (Neritrema) arcana Hannaford Ellis, 1978	Ravenscar, UK	15
	Robin Hoods Bay, UK	15
Littorina (Neritrema) saxatilis (Olivi, 1792)	Venice, Italy (type loc.)	15
	Robin Hoods Bay, UK	15
	Ravenscar, UK	15
	São Miguel, Azores	15

RESULTS

All specimens of *L. saxatilis*, *L. arcana* and *L. compressa* had the same monomorphic Mb profile, both with PAGE (Fig. 1) and IEF (Fig. 2). These profiles corresponded with the *L. saxatilis* profile reported by Medeiros et al. (1998), while the alternative Mb profile, said to be typical of *L. arcana* (Medeiros et al. 1998: figs 2, 4), was not observed here.

Both PAGE (not shown) and IEF revealed that *L. scutulata* and *L. plena* have identical Mb profiles, which resemble that of *L. saxatilis*, except for the fact that with IEF the whole *L. saxatilis* Mb profile was slightly shifted toward a higher pH (Fig. 3). *L. keenae*, on the contrary, had a very different Mb profile which was shared with *L. striata*. Yet, with IEF *L. striata* revealed an additional Mb fraction at a pI of about 4.6, which was not observed in the other littorinids studied here (Fig 3). On the other hand, *L. striata* and *L. keenae* showed a more or less strong Mb band at a pI around 6.3. This band was lacking in the subgenera *Littorina* and *Neritrema*, but was present in *N. hawaiiensis*, *C. muricatus* and *M. neritoides*. For the remainder the IEF profiles of *N. hawaiiensis* and *C. muricatus* were similar to those of *L. keenae* and *L. striata*, although they did not show the Mb fraction at pI 4.6 of *L. striata* (Fig. 4). Finally, similar to the results of Medeiros et al. (1998), the Mb profile of *M. neritoides* was indistinguishable from that of *L. striata* with PAGE (not shown), but appeared to be distinct with IEF (Fig. 3).

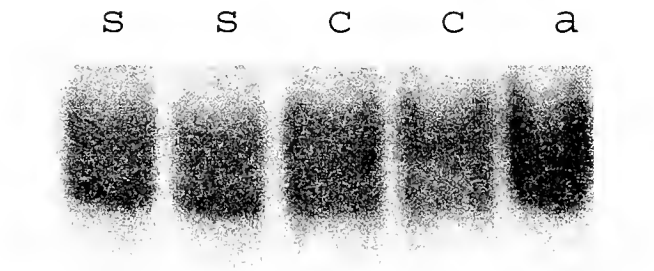

Figure 1. Benzidine staining of PAGE profiles of radular Mb in *L. arcana* (a), *L. compressa* (c) and *L. saxatilis* (s).

Surprisingly, in contrast to the apparent Mb monomorphism of *C. muricatus* revealed by IEF, PAGE of the same individuals yielded a tentative Mendelian polymorphism reminiscent of a monomeric protein coded by a single locus with two alleles (Fig. 5).

DISCUSSION

The present analyses show that the alleged species specific Mb differentiation between *L. saxatilis* and *L. arcana* (Medeiros et al. 1998) is not foolproof, since the *L. saxatilis* profile also occurs in *L. arcana*. Hence, as Medeiros et al. (1998) screened only one population of *L. arcana* (from Great Castle Head near Dale Fort, UK) and did not apply the KCN protocol to reduce artificial Mb variation, it seems worthwhile to screen a new batch of animals from this population in order to confirm the existence of two electrophoretic Mb types in *L. arcana*.

The fact that *L. scutulata* and *L. plena* have identical Mb patterns is not surprising, given the close relationship between both species (Mastro et al. 1982, Murray 1982, Reid 1996, Rugh 1997). It is however, interesting that the Mb profile of these two species differs from that of *L. saxatilis*, *L. arcana*, *L. compressa*, and *L. littorea* (this latter by inference from Medeiros et al. 1998), while

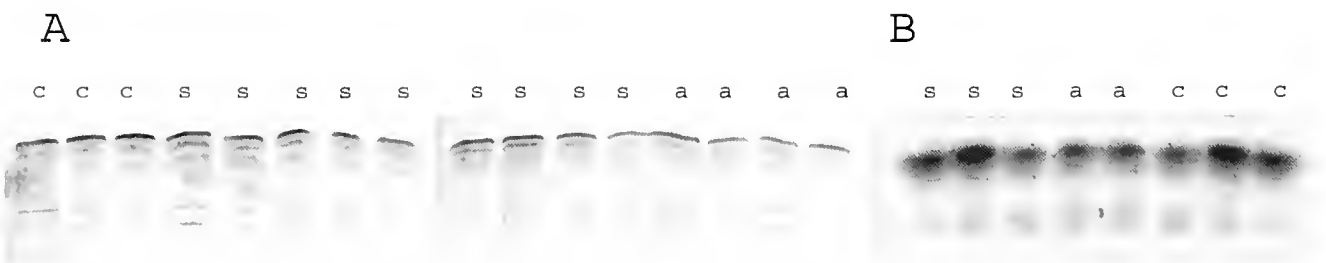

Figure 2. IEF profiles (pH 4–6.5) of radular Mb in *L. arcana* (a), *L. compressa* (c) and *L. saxatilis* (s), stained with Coomassie Brilliant Blue (A) and benzidine (B).

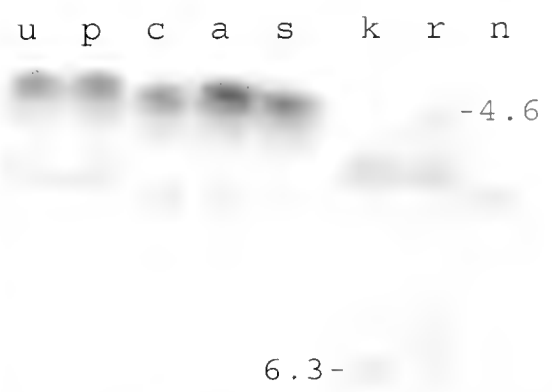

Figure 3. Benzidine staining of IEF profiles (pH 4-6.5) of radular Mb in *L. arcana* (a), *L. compressa* (c), *L. keenae* (k), *M. neritoides* (n), *L. plena* (p), *L. striata* (r), *L. saxatilis* (s), and *L. scutulata* (u). The arrow indicates the special band at pH 4.6 in *L. striata*; the triangle indicates the band at pH 6.3.

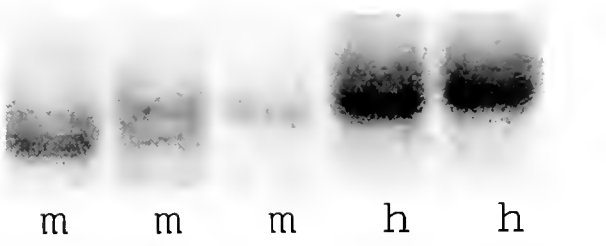

Figure 5. Benzidine staining of PAGE profiles of radular Mb in *C. muricatus* (m) and *N. hawaiiensis* (h). Note the suggestive Mendelian-like variation in *C. muricatus*.

the Mb profiles of *L. keenae* and *L. striata* differ even more conspicuously from the Mb profile of these four species. Instead the Mb profiles of *L. keenae* and *L. striata* are similar to those of *Nodilittorina* spp., *Littoraria* spp. and *Cenchritis* sp. reported here and by Medeiros et al. (1998). These data are consistent with current taxonomic practice to place *L. striata* and *L. keenae* in the separate monotypic subgenera *Liralittorina* and *Planilittorina* (Reid 1996), such that the Mb pattern of *L. keenae* could have been derived from that of *L. striata* by the loss of the supposedly autapomorphic Mb band at pI 4.6 in *L. striata*. The Mb profile of *L. scutulata* and *L. plena* would then represent a synapomorphy distinguishing both species from the other *Littorina* and *Neritrema* species, while Mb profiles of *L. littorea*, *L. saxatilis*, *L. compressa* and *L. arcana* would unite the subgenera *Littorina* and *Neritrema*. Finally, the Mb patterns reported by Medeiros et al. (1998) for *L. arcana* (if correct), *L. fabalis* and *L. obtusata* may involve still further derived states. Given that in the consensus phylogeny of the genus *Littorina* (Reid 1996: Fig. 119) *L. scutulata* and *L. plena* form an independent clade (making the subgenus *Littorina* paraphyletic), our Mb data support the suggestion that these latter two species may constitute a separate subgeneric group.

Although this scenario fits the currently accepted phylogeny of the genus *Littorina*, the Mb patterns are also compatible with the alternative idea that *L. striata* may be not a *Littorina*. Yet, in that case *L. keenae*, whose assignment to *Littorina* has never been challenged, would become the most basal branch of the genus, suggesting that a *Nodilittorina/Littoraria*-like Mb profile (like in *L. striata* and *L. keenae*) is not a priori inconsistent with the genus *Littorina*. However, since electrophoretic mobilities are not reliable to infer homology and/or identity, the present Mb data are essentially phenetic. Hence apparent similarities may not necessarily indicate common descent, particularly not in a molecule like Mb which may be subject to functional constraints that may cause homoplasy. Nevertheless, the Mb data do suggest that a sequence analysis at the amino acid and nucleotide level could help to understand littorinid phylogeny and functional ecology. Such studies have been done for abalones (Suzuki et al. 1997) and anaspids (Rinaldi & Ophir 1998)

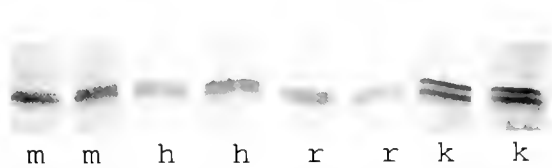

Figure 4. Coomassie Brilliant Blue staining of IEF profiles (pH 4-6.5) of *N. hawaiiensis* (h), *L. keenae* (k), *C. muricatus* (m), and *L. striata* (r).

Finally, the IEF Mb data on *N. hawaiiensis* and *C. muricatus*, add to the Mb monomorphism in the genera *Littoraria* and *Nodilittorina* (Medeiros et al. 1998) and extend this observation to the genus *Cenchritis*. However, they contradict the alleged species specific Mb variation in *Littoraria* and *Nodilittorina* as reported by Jones (1972), who used PAGE. Probably this discrepancy is due to technical issues and/or hidden Mb heterogeneity. Indeed, when we applied PAGE in *C. muricatus*, we also detected variation that was not uncovered by IEF. Hence, combined with the observations of Medeiros et al. (1998) on the hidden PAGE differentiation in *M. neritoides* that was resolved by IEF, it is obvious that PAGE and IEF are complementary in the analysis of littorinid Mb variation. However, whether the *C. muricatus* patterns really involve a Mendelian polymorphism, needs further scrutiny in view of the confusing evidence on the genetic background of littorinid Mb (Olabarria et al. 1998).

In conclusion, the present data confirm Medeiros et al.'s (1998) claim that littorinid Mb are useful systematic markers that can provide the same kind of information as do the haemoglobins in freshwater snails (Bailey et al. 1986) and fishes (e.g. Basaglia & Callegarini 1987, Macaranas et al. 1996, Rizzotti & Gioppato 1999), or the haemocyanins in terrestrial gastropods (e.g. Symondsen & Walton 1994) and crustaceans (e.g. Mangum 1996, Mangum & McKenney 1996). Nevertheless, littorinid Mb are less suited to differentiate closely related species, but on the other hand seem quite informative for higher level systematics. Unfortunately, the present knowledge on littorinid Mb is still far too scanty to fully exploit them for ecophysiological, population genetic, taxonomic and phylogenetic investigations.

ACKNOWLEDGMENTS

We are indebted to J. Grahame, P. Mill, C. Van Osselaer, C. Wilding, and B. Winnepenninckx for their help in obtaining specimens. The constructive comments of two anonymous referees greatly improved the manuscript. HERITABILITY OF SHELL TRAITS IN WILD *LITTORINA SAXATILIS* POPULATIONS: RESULTS ACROSS A HYBRID ZONE

MÓNICA CARBALLO,[1] CARLOS GARCÍA,[2] AND EMILIO ROLÁN-ALVAREZ[1]*

[1]*Departamento de Bioquímica, Genética e Inmunología, Facultad de Ciencias, Universidad de Vigo, 36200 Vigo, Spain;* [2]*Departamento de Biología Fundamental, Facultad de Biología, Universidad de Santiago de Compostela, 15706 Santiago de Compostela, Spain*

ABSTRACT There is a hybrid zone in *Littorina saxatilis* from exposed Galician rocky shores (northwest Spain) where two ecotypes, ridged and banded and smooth and unbanded are found to be associated with distinct habitats and shore levels. On the mid-shore, however, the two ecotypes and a variable percentage of hybrids can be found in sympatry. Furthermore, many shell traits present a clinal distribution along the vertical environmental gradient within ecotype, although very little knowledge about its genetic basis is available. This species is viviparous, and every female has a brood pouch containing many embryos. This makes it possible to use the shelled embryos from the brood pouch of every female to estimate the heritability of morphological traits (by full-sib correlation and offspring–mother regression). We took seven samples of 20 females across two vertical transects and found significant heritabilities for most shell traits and a multivariable factor score. The average narrow-sense heritability was 0.102, and the average broad-sense heritability was 0.489, although the present estimates can be somewhat biased. The high correlation observed between the genotypic variance (estimated by full-sibs correlation) and the additive variance (estimated by offspring–mother regression) as well as the similar results obtained after transforming the variables correcting for scale effects support the existence of a common additive genetic component in both kinds of heritability. Genetic variability significantly differed between shore levels. Interestingly, hybrids did not show an increase in genetic variability with respect to both pure ecotypes, which perhaps suggests that natural selection is eroding their variability. These results complement a previous claim about the adaptive shell polymorphism in Galician *L. saxatilis* populations

KEY WORDS: natural selection, hybridization, clinal variation, genetic variability, shell polymorphism, embryo shell

INTRODUCTION

Littorina saxatilis (Olivi) is a polymorphic species from North Atlantic intertidal shores (Fretter & Graham 1980). The species inhabits a wide range of different ecological niches, from estuaries to rocky shores or even salt marshes (Reid 1996). Coupled with these habitat differences there is a known morphological and behavioral population differentiation, which has been traditionally interpreted an as example of adaptive polymorphism (Janson 1983, Reid 1993, reviewed in Reid 1996). However, to be adaptive, a polymorphism must be first heritable (Endler 1986), which is usually a priori assumed in natural populations without further experimental evidence. A few studies have tried to estimate the proportion of genetic vs. phenotypic variability by rearing families in the laboratory (Johannesson & Johannesson 1996, Ward et al. 1986, Ward et al. 1991, Warwick 1983, Warwick et al. 1990), but this approach is troublesome, very time consuming, and, for some ecotypes (sensu Turesson 1922), very difficult (see Warwick et al. 1990). Yet, Newkirk and Doyle (1975) have suggested applying classical quantitative genetics methods to estimate genetic variances for quantitative traits in wild populations of this and other species with similar life-history characteristics. Because *L. saxatilis* females usually carry a brood pouch with many embryos (Fretter & Graham 1980, Reid 1996), pregnant wild females can be used as different families of full sibs, from which full-sib correlation and offspring–mother regression allow us to estimate the genetic variances for different shell traits (Falconer & Mackay 1996). Newkirk and Doyle (1975) found significant genetic differentiation between *L. saxatilis* populations allocated along an estuarine gradient. They found the lower genetic variability in those traits and population more affected by natural selection. They suggested that their polymorphism was maintained by natural selection.

On exposed Galician rocky shores, two sympatric ecotypes can be found associated with two different habitats (Johannesson et al. 1993): The ridged and banded form (RB) is usually found on upper shores among barnacles, whereas the smooth and unbanded form (SU) is typically found on lower shores among mussels. On the mid-shore, both barnacles and mussels overlap forming a patchy habitat in which both pure forms and some (5–40%) phenotypically intermediate forms (HY) can be found even copulating together. Every ecotype (RB, HY, and SU) partially aggregates in the mid-shore, showing particular preferences for different microhabitats (Otero-Schmitt et al. 1997). In fact, they do not mate randomly on the mid-shore, showing a noticeable but still incomplete assortative mating among ecotypes (Johannesson et al. 1995). The two ecotypes differ for many morphological, physiological, and behavioral traits (Erlandsson et al. 1998, Johannesson et al. 1993, Johannesson et al. 1997, Rolán-Alvarez et al. 1996, Rolán-Alvarez et al. 1997). Particularly, they show striking differences in shell size, morphology, and color polymorphism. Besides, this sharp ecotype distribution (an ecotone sensu Endler 1986), a more typical clinal distribution (sensu Endler 1986) across the shore gradient, can be found for many morphological traits within an ecotype (Cruz 2000). A genetic basis behind the presence of shell bands and ridges has been shown because females of each morph produce progeny of the same characteristics under laboratory conditions (Johannesson et al. 1993). However, there is no such proof for other quantitative traits or for quantitative estimates of the relative importance of genetic variability behind other shell differences. This information is fundamental if we want to understand fully the evolutionary forces that have modeled the observed ecotone and clines in shell traits along the environmental gradient.

We used the Newkirk and Doyle (1975) approach to estimate the heritability for different shell traits in wild populations of the Galician hybrid zone. We analyzed replicated transects along the vertical gradient and compared the results by full-sib correlation and mother–offspring regression. Because we are studying the

*Corresponding author. E-mail: rolan@uvigo.es

trends in genetic variability on a zone where hybridization occurs (Johannesson et al. 1993, Rolán-Alvarez et al. 1996), we would expect that hybrids from mid-shore present some increase of their genetic variance due to hybridization for those traits being genetically differentiated between upper and lower shore populations. This latter null hypothesis assumes that the hybrid populations are stable and fertile (Johannesson et al. 1995). However, the results seem to contradict this expectation, suggesting that natural selection may be eroding the genetic variability in the hybrids or, alternatively, that the assumptions of such a model are false.

MATERIALS AND METHODS

Sampling

Adult *L. saxatilis* were sampled in June 1998 from two different localities, Centinela and Senín (separated by 3 km). They were picked along two vertical transects in intertidal rocky shore areas and five different samples (quadrats) within the transect (Fig. 1). Upper shore and upper mid-shore samples and lower shore and lower mid-shore samples covered the whole range of pure RB and SU populations, respectively. Upper mid- and lower mid-shore samples were closer to mid-shore samples (1–3 m) than to their respective upper or lower shore samples (4–10 m). In each sample, 100 snails (larger than 3 mm) within a 30–50 cm diameter circle were obtained and stored at −70°C. Later, they were randomly chosen from the sample, dissected, and sexed. The first 20 females with embryos within their brood pouch were used for the morphological study. The mid-shore sample included similar frequencies of RB, SU, and HY individuals. However, due to the low frequency of natural hybrids, it was not possible to obtain 20 pregnant HY females per sample (see Fig. 1). To avoid an unbalanced experimental design, hybrid data were excluded from some analyses (see below). Finally, 120 females (families) and 360 embryos of RB, 120 females and 360 embryos of SU, and 24 females and 72 embryos of HY were employed.

Morphological Variables

The shell of the female and the three largest embryos within their brood pouch were placed in an apertural top view and digitized to make several measurements (Fig. 2): shell height (SM1), aperture height (SM3), aperture width (SM4), and width of first spire whorl (SM7) following Cruz, Carballo and Rolán-Alvarez (submitted); distance from the center of the first whorl to the apex (Y) and ratio of the first whorl (R) following Newkirk and Doyle (1975); and top shell diameter (SD) and top aperture width (AW) following Rolán-Alvarez et al. (1996). Adult RB individuals were measured with an error of 0.0096 mm (eight magnifications required), adult SU individuals were measured with an error of 0.0042 (12.5 magnifications required), and both RB and SU embryos were measured with an error of 0.0016 mm (80 magnifications required) by a Leica MZ12 stereoscopic microscope. We statistically analyzed the parameter T (Y/R) and S (SM4/SM3), the latter with small modifications from Newkirk and Doyle (1975). We also used the distance from the end of first whorl to the apex (SM15) and the parallel to the maximum aperture length (SM16). Genetic analyses were accomplished on individual variables but also on a multivariable factor score obtained by principal component analysis. Classical statistical analyses and multivariable methods were done by the SPSS/PC package (version 9.0.1).

Genetic Analysis

The individual variables from embryo data were analyzed with a two-way nested analysis of variance (ANOVA) including the factor *shore level* (fixed; upper, upper-mid, lower-mid, and lower), the factor *locality* (random; Senín and Centinela), and the factor *family* (random; nested within the shore level × locality interac-

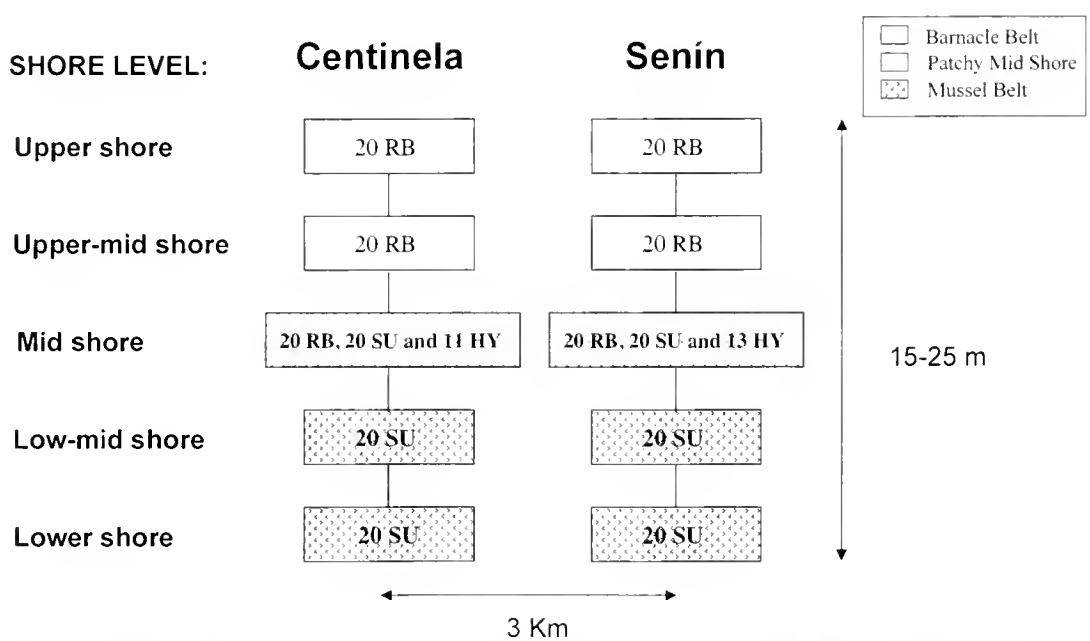

Figure 1. Sampling design. Every sample (quadrat) represents 20 adult females and the three largest embryos within their brood pouch, except in mid-shore samples where we tried to obtain 20 ridged and banded (RB), smooth and unbanded (SU), and phenotypically intermediate (HY) specimens. Upper shore samples were obtained on the barnacle belt, and lower shore samples were obtained on the mussel belt. Mid-shore samples where obtained in the patchy barnacle/mussel zone.

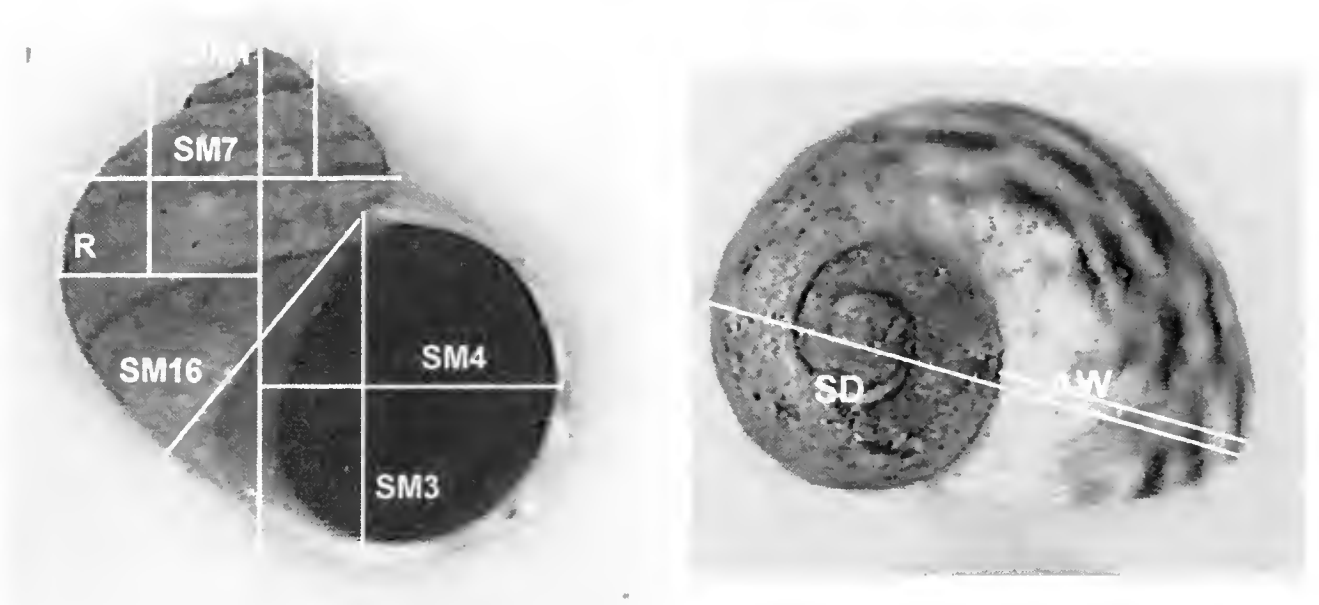

Figure 2. The morphological measurements studied on a smooth and unbanded (SU) individual. SM1, shell height; SM3, aperture height; SM4, aperture width; SM7, width of the first spire whorl; SM15, distance from the end of first whorl to the apex; SM16, the parallel to the maximum aperture length; R and Y following Newkirk and Doyle (1975); SD, top shell diameter; AW, top aperture width.

tion) on upper and lower shore samples. A second nested ANOVA was performed on mid-shore samples with the factor *morph* (fixed; RB and SU), the factor *locality* (random; Senin and Centinela), and the factor *family* (random; nested within the *morph* × *locality* interaction).

We assumed that embryos from the same brood pouch were true full sibs following Newkirk and Doyle (1975). These authors analyzed 12 independent groups of brood pouch embryos for an esterase polymorphism (with four alleles) and found that the embryos were full sibs in all cases except one (but see Newkirk & Doyle 1979). This assumption, if false, implies an underestimation of the heritability (it could be up to twice the observed amount). To minimize the risk of heterogeneity in progeny we used the three largest embryos (similarly sized) in every female. Classical genetic analyses of full sibs (ANOVA model 1) and offspring–mother regression were done following Falconer and Mackay (1996). The covariance between full-sib is one half of the additive variance plus one quarter of the dominance variance plus the variance due to the common environment, whereas the covariance between offspring and mother is exclusively one half of the additive variance. The former relationship can be used to obtain an estimate of the broad-sense heritability, whereas the latter allows us to obtain an estimate of the narrow-sense heritability. However, complex interactions and maternal effects may somewhat bias these estimates. For example, the phenotypic value of the mother for the character in question can directly influence the same character in the offspring. This effect can produce biases simultaneously in both full-sib correlation and offspring–mother regression. Another possible source of bias is the genotype–environment interaction, due to some environments causing intrinsically larger genotypic variability than others.

Snails from different shore levels usually have different average sizes (Johannesson et al. 1995). We have accomplished different statistical corrections to minimize this scale effect. First, we have preferentially used coefficients of variation rather than the heritability to compare results from different methods and samples (Sokal & Rohlf 1995, Houle 1992, Falconer & Mackay 1996). Furthermore, we have incorporated a transformation that corrects the scale effects between samples, using the linear regression of the mean against the standard deviation in every sample as suggested by Falconer and Mackay (1996). The transformation is $X = \log (x + a/b)$, where X is the transformed variable, x is the original variable, and a and b are the intercept and the slope of the linear regression of the mean on its standard deviation.

The comparison between mother and offspring measurements may be biased by other causes because the analyses assume that the two sets of data are obtained in individuals of the same age and for the same trait. The former is not true in our case, causing at best a scale effect (allometry) between mother and offspring. To avoid this, we repeated the analyses using the transformation suggested by Lynch and Walsh (1998) to correct for allometry with respect to size. The transformation uses the algorithm $Y = a^*X^b$, where a and b are the intercept and the slope, respectively, of the regression of the trait with the shell height. The residual of such a regression for every data point can be used to study the variation of the trait corrected for allometric effects (Packard & Boardman 1987).

RESULTS

The two-way nested ANOVA for individual variables presented in Table 1 show that the factor *shore level* was significant for most traits, whereas the factors *locality* and the *interaction* were significant only in a few cases. The factor *family* was significant in all cases, which may perhaps be due to genetic effects (see also below). In most cases we tried to correct for heteroscedasticity by using the square root or logarithmic transformations, succeeding for SM1, SM4, SD, and S. Therefore, for other traits, type I error must be taken with caution. Similarly, we found differences in the factors *morph* and *interaction* for most traits in mid-shore samples. Again we used square root and logarithmic transformation to correct for heteroscedasticity, being unsuccessful only with S. Similar results were obtained with the transformation

Abbreviations: SM1 = shell height; SM3 = aperture height; SM4 = aperture width; SM7 = width of the first spire whorl; SM15 = distance from the end of the first whorl to the apex; SM16 = the parallel to the maximum aperture length; SD = top shell diameter; AW = top aperture width; T = parameter (Y/R); S = SM4/SM3.

In the upper/lower data set the fixed factor is *shore level* (upper, upper-mid, lower-mid, and lower shore samples), whereas in the mid-shore data set the fixed factor is *morph* (ridged and banded vs. smooth and unbanded). In both cases the ANOVA incorporate the random factor *locality* (Senín and Centinela), the corresponding interaction, and the nested factor *family* (within the interaction). The analyses used 20 families per sample and three embryos per family. Hybrid families were excluded to avoid unbalanced designs.

of Falconer and Mackay (1996) (correcting for scale effects among samples) as well as traits divided by shell height (not shown). This suggests extensive morphological differences across shore levels and morphs, as well as among families, for most shell traits.

The genetic coefficient of variation and the heritability are presented for the measured variables across the environmental gradient in Table 2 for both full-sib and offspring–mother regression methods. The averages for the two localities are presented, with the significant cases designated by lowercase letters (with significant cases determined after sequential Bonferroni corrections underlined) in Senín (a) and Centinela (b), respectively. Furthermore, estimated heritabilities were much larger in full-sib analyses (broad-sense heritability) than in offspring–mother analyses (narrow-sense heritability). This may be caused by some contribution of maternal plus dominance effects to the full-sib resemblance but not to the offspring–mother resemblance. A more useful statistic to compare genetic variances between samples and methods may be the coefficient of variation, which partially corrects for scale effects. Interestingly, the coefficient of genetic variance (in full sibs) and the coefficient of additive variance (in mother–offspring regression) were highly correlated for most shell traits across shore levels (Table 2), suggesting a common component (probably the additive) in both kinds of estimates. Besides, the estimates seem to fall into two categories, upper or upper mid-shore samples (typical RB samples from upper shore), with very low coefficients of genetic variation and samples from mid- to lower shore with larger coefficients of genetic variation (Table 2). Scale effects may not cause these differences because those populations with the smallest variances had the greatest means for all measured variables. On the mid-shore another trend emerged: The coefficient of genetic variation of hybrids is never clearly larger than the corresponding estimates for both RB and SU ecotypes (Table 2). The values for hybrids are usually smaller or intermediate between pure ecotypes, which is exactly the opposite of that we would expect under a null hypothesis of hybridization for neutral genetic variability. The transformation of Falconer and Mackay (1996) for full sibs and the transformation of Lynch and Walsh for offspring–mother regression, which corrected for scale effects among samples and for embryo-adult allometry, respectively, rendered similar results in all variables: significant heritabilities for some traits and the same two trends mentioned above.

We could successfully reduce all the variables by principal component analysis of females. The first principal component (PC1) represented 79.9% of the overall variability. The relationship between the two main components (PC1 and PC2) is represented in Figure 3 for all females included in the analyses. The PC1 acts like a discriminant function between RB and SU morphs, having a clear biological meaning (a summary variable for all the morph differences). Figure 4 shows the coefficient of genetic variance (estimated from full-sib correlation) and the coefficient of additive variance (estimated from offspring–mother regression) for PC1 across shore levels. The estimates across sampling points were highly correlated ($n = 14$; $r = 0.832$, $P = 0.000$), which suggests that there is an important component of the covariance between relatives (probably the additive) in common (Fig. 4). Furthermore, this relationship was maintained when we used the Falconer and Mackay (1996) transformation to correct for scale effects among samples ($n = 14$; $r = 0.863$, $P = 0.000$). This supports the differences between shore levels in genetic/additive variances, although at present we cannot exclude some minor bias due to genotype–environment interaction or maternal effects. Again, the genetic variance estimates by full-sib correlation were larger than the additive variances estimated by offspring–mother regression, suggesting that maternal or dominance effects significantly contribute to the resemblance between relatives in the former. Interestingly, we observe the same two trends discussed above (Fig. 4) that upper and upper-mid populations presented significantly smaller genetic variances and that hybrids did not show an increase of genetic variances as would be expected under neutral hybridization.

DISCUSSION

Many studies have reported morphological, behavioral, and physiological polymorphism in littorinids (reviewed in Reid 1996). In some cases, laboratory experimentation, computer simulations, and natural studies have shown that natural selection may account for some of this polymorphism (Strushaker 1968, Janson

In every sample we measured 20 adult females and the three largest embryos per female. The estimates are the mean across localities. The letter "a" represents significant heritability estimates, by analysis of variance (ANOVA) for Centinela samples ($P \leq 0.05$), and the letter "b" represents significant genetic variability estimates (by ANOVA) for Senin samples ($P \leq 0.05$). The F tests differed between full sibs ($df_1 = 19$; $df_2 = 40$) and offspring-mother ($df_1 = 1$; $df_2 = 18$) data sets (see also MATERIALS AND METHODS). Significant cases after sequential Bonferroni multitest corrections for the 14 different estimates within trait (Rice 1989) are underlined. **Significant Pearson correlation ($p < 0.01$) between the coefficient of genetic variance (in full sibs) and the coefficient of additive variance (in mother-offspring regression).

Abbreviations: SM1 = shell height; SM3 = aperture height; SM4 = aperture width; SM7 = width of the first spire whorl; SM15 = distance from the end of the first whorl to the apex; SM16 = the parallel to the maximum aperture length; Y = distance from the center of the whorl to the apex; R = ratio of the first whorl; SD = top shell diameters; AW = top aperture width; T = parameter (Y/R); S = SM4/SM3.

1983, Boulding 1990, Rolán-Alvarez et al. 1997), but only in a few cases is there data showing a genetic basis for the studied traits (Strushaker 1968, Murray & Clark 1966, Reimchen 1979, Boulding & Hay 1993, Johannesson & Johannesson 1996). The low frequency of studies showing genetic variability for the phenotypic polymorphism in the wild is frustrating because it is a serious drawback of any adaptive hypothesis. Besides, there is a theoretical good chance to be successful (nearly all examined quantitative traits have shown genetic variation; Falconer & Mackay 1996). Here, we have attempted quantitative genetic estimates (heritabili-

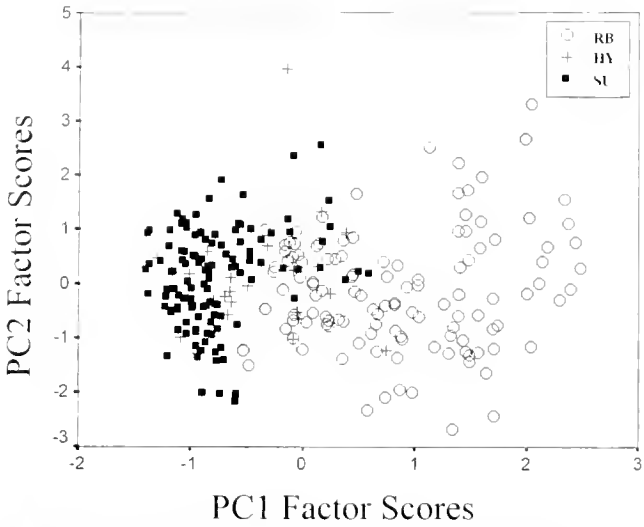

Figure 3. Relationship between principal component (PC)1 and PC2 factor scores in adult females.

ties) from wild populations of Galician *L. saxatilis* populations. The results clearly show that there is some genetic variability under the shell traits measured (Tables 1 and 2; Fig. 4). We found a mean narrow-sense heritability of 0.102 (mean of significant offspring–mother heritabilities) and a mean broad-sense heritability of 0.489 (mean of significant full-sib heritabilities) for the shell traits studied in our populations of *L. saxatilis*. However, our quantitative estimates may be somewhat biased by nongenetic effects. The resemblance between mother and offspring may underestimate the heritability due to scale effects of individual variables because adult and embryo measurements differ in one order of magnitude. Besides, if a small percentage of the embryos studied were half sibs rather than full sibs, these heritability estimates would be underestimated as well. On the other hand, the resemblance between full sibs may overestimate the heritability because it also includes the common environmental component. Maternal

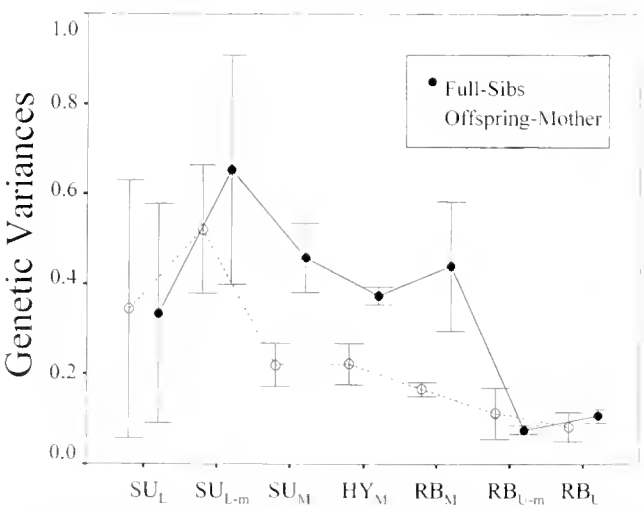

Figure 4. Trends of genetic variances (and their standard deviations) across shore levels and samples for principal component (PC)1 from full-sib correlation and offspring–mother regression analyses. effects could bias both estimating methods simultaneously, but this would usually occur in traits that are directly related to an embryo's fitness rather than to morphological traits. Maternal effects are assumed to be important mainly in vertebrates (Falconer & Mackay 1996). Due to the possible bias mentioned above, perhaps a more realistic narrow-sense heritability estimate would be the average between both estimates (0.296). Similar heritabilities (slightly larger) were found for morphological traits in other littorinids (Boulding & Hay 1993) and *Drosophila* (Houle 1992). The coefficient of genetic variation obtained for T and S were of similar magnitude than that obtained by Newkirk and Doyle (1975) in *L. saxatilis* populations from Halifax. These results complement our previous adaptive interpretation with respect to the Galician shell trait polymorphism by disruptive natural selection favoring each morph at different shore levels (Johannesson et al. 1993, Rolán-Alvarez et al. 1997).

The additive and genetic variability of different shell traits varied across the environmental gradient (the hybrid zone; see Table 2 and Fig. 4). In fact, upper and upper mid-shore populations showed lower additive or genetic variability than the rest of populations (Table 2; Fig. 4). These differences could be partially caused by phenotypic plasticity, a term used to include all nongenetic changes in the phenotype (genotype–environmental interactions, for example) that improve individual fitness. There are, in fact, important differences between upper and lower shore levels for many physical and biological parameters (Johannesson et al. 1993, Rolán-Alvarez et al. 1997). Phenotypic plasticity has been also shown in other littorinids (Kemp & Bertness 1984, Boulding & Hay 1993) and may have a nontrivial role in many *L. saxatilis* polymorphisms (Boulding 1990). However, the differences in genetic variances across shore levels were observed after correcting for scale effects (using both the coefficients of variation and the logarithmic transformed variables). This transformation may remove or at least diminish most interaction terms (including genotype–environment interactions) contributing to the resemblance between relatives (Falconer & Mackay 1996). Furthermore, we have obtained a significant correlation between the coefficient of genetic (estimated from full-sibs correlation) and the coefficient of additive variation (estimated from offspring–mother regression). These facts may suggest that the differences in coefficient of variation across shore levels may not be significantly biased by phenotypic plasticity, maternal effects, or other factors because the only expected component in common between these two kinds of estimates is the additive variance component. In summary, upper shore populations showed smaller genetic variability than the rest of populations. We can hypothesize that natural selection (which can erode the genetic variability of a population; see Newkirk & Doyle 1975, Falconer & Mackay 1996) may act stronger (at least in summer) on upper shores than on mid/lower shores (perhaps due to sun and desiccation stresses as well as crab predation; see Rolán-Alvarez et al. 1997). Nevertheless, to properly quantify genetic variances and phenotypic plasticity, we should do a breeding laboratory experiment to partition the familiar variance in different causal components (e.g., additive and dominance components, maternal effects, or genotype–environmental interactions).

Another interesting trend is observed on the mid-shore, where hybrids had coefficients of genetic variation or coefficients of additive variation intermediate or even lower than the same estimates in both pure morphs (Table 2; Fig. 4). These differences between morphs (RB vs. SU) were maintained when comparing populations from different habitats (upper vs. lower shore) and

populations from the same habitat (RB vs. SU from mid-shore), which suggests that the differences may not be caused by genotype–environment interactions. The observed trend was the opposite of that we would expect under hybridization of genes fixed at different shore levels or ecotypes (RB vs. SU ecotypes from mid-shore), assuming that hybrid populations are stable and at least partially fertile (Johannesson et al. 1993, Johannesson et al. 1995, Rolán-Alvarez et al. 1997, Rolán-Alvarez et al. 1999). One explanation for the low frequency of hybrids would be that hybrids are rather true F_1 hybrids unlikely to produce viable progeny. In such circumstances, the population of hybrids would be replaced every generation and would have lower genetic variability. However, embryos from female F_1 hybrids are actually F_2 hybrids; thus, we have estimated our genotypic variances at least from F_2 hybrid populations. In summary, the results suggest that several factors may be eroding the genetic variability of the hybrid populations (probably a complex mixture of hybrid genotypes). The main factor may be natural selection, with hybrids adapted to microhabitats slightly different from those of both pure ecotypes. This process of adaptation will necessarily cause some loss of the original genetic variability in the hybrid population (Falconer & Mackay 1996). A similar effect has been described in other hybrid zones; although endogenous hybrid unfitness may be the most common process on hybrid zones (tension zones sensu Barton & Hewitt 1989), hybrid amelioration (sensu Ritchie & Hewitt 1995) could explain these results if some hybrid genotypes are favored with respect to others on the mid-shore (eroding their overall genetic variability). We are presently involved in laboratory experimentation attempting to obtain F_1 hybrids and quantitative genetic estimates for the same shell traits presented above, which may help to resolve many of the questions regarding the dynamics of this hybrid zone.

DIET IN MANGROVE SNAILS: PRELIMINARY DATA ON GUT CONTENTS AND STABLE ISOTOPE ANALYSIS

J. T. CHRISTENSEN,[1]* P.-G. SAURIAU,[2] P. RICHARD,[2] AND P. D. JENSEN[1]

[1]*Department of Marine Ecology, Institute of Biological Sciences, University of Aarhus, Finlandsgade 14, DK-8200 Aarhus N, Denmark;* [2]*Centre de Recherche en Ecologie Marine et Aquaculture de L'Houmeau (CREMA) (CNRS-IFREMER UMR 10) BP 5, F-17137 L'Houmeau, France*

ABSTRACT Microscopic analysis of gut contents performed on three *Littoraria* species from mangrove forests in Thailand revealed differences in diet among species. Analysis of carbon and nitrogen stable isotopes was used as an alternative way of tracing food sources. *Rhizophora* leaves, scrapings from both leaf and prop-root surfaces, and local particulate organic matter (POM) were well separated on the basis of their $\delta^{13}C$ and $\delta^{15}N$ values. In contrast, the three *Littoraria* species exhibit considerable overlap and scatter in both carbon and nitrogen isotope ratio values, suggesting that the snails are opportunistic feeders sharing similar food resources. The wide range of $\delta^{13}C$ values of *Littoraria* (−17.2‰ to −26.3‰) is consistent with carbon assimilation from multiple sources (epiphytes from leaves and prop roots, suspended POM, and *Rhizophora* detritus). *Littoraria intermedia* and *L. pallescens*, the smallest species, had similar $\delta^{13}C$ values, whereas *L. scabra* was significantly more ^{13}C depleted. A diet of microalgae and cork cells from prop roots could explain this pattern, with *L. scabra*, being larger, consuming relatively more cork cells. However, only a few of the *L. scabra* and *L. intermedia* individuals had $\delta^{15}N$ values consistent with such a diet, and the remaining *L. scabra* and *L. intermedia* and all *L. pallescens* individuals were too depleted, indicating that these individuals must derive a significant amount of their food from a strongly ^{15}N-depleted source. Such a source is present on *Rhizophora* leaf surfaces ($\delta^{15}N = 0.30 \pm 0.05$; $n = 2$). Some very low values of *Littoraria* $\delta^{15}N$, down to −7‰, indicate that some individuals have assimilated a yet unknown, highly ^{15}N-depleted food source or that other unknown fractionation processes are involved.

KEY WORDS: *Littoraria*, diet, mangroves, stable isotopes, $\delta^{13}C$, $\delta^{15}N$

INTRODUCTION

Mangrove snails of the littorinid genus *Littoraria* are found throughout the tropics with an especially large number of species in the Indo-Pacific region (Reid 1986, Reid 1989). Indo-Pacific species all have planktonic larvae and spend their adult lives on stems, prop roots, and leaves of the trees. Like most littorinids they feed on biofilms, and the mangroves presumably act merely as substrates.

Littoraria scabra (L., 1758), *L. intermedia* (Philippi, 1846), and *L. pallescens* (Philippi, 1846) have been studied in Thailand, where their stomachs have been found to contain fungal hyphae and spores, among other items (Christensen 1998). *L. scabra* and *L. intermedia* live on stems and prop roots of mangroves with *L. scabra* found lower and usually on the seaward edge of the forests. *L. pallescens* is found mostly on the leaves of mangroves where *L. intermedia* is also occasionally seen. *L. pallescens* feeds on the leaf surface without damaging the leaf epidermis, although crescent-shaped necrotic marks may be seen on leaves where the snails rest during the day. However, Ohgaki (1990) reported radular marks on leaves of *Rhizophora stylosa*. The snails move up and down with the tides and come in direct contact with the water only when releasing offspring. The zonation of the three species may be seen as degrees of terrestrialization of snails with marine origins, and it is therefore interesting to compare their diets.

Direct microscopic analysis of gut contents may reveal the range of food items ingested by animals, but the method has certain drawbacks. First of all, the method will depend strongly on the skills of the observer with respect to identifying fragmented objects. Indeed, most of the material in the gut contents of animals may not be visually identifiable. Hard structural tissues may be more easily identified than soft tissues, resulting in a bias in the relative importance of items, and this bias may be further enhanced by differences in degradability. Finally, gut contents analysis does not reveal the extent to which food items are actually assimilated.

Stable isotope analysis of animal tissues can provide alternative information on sources of food. The stable carbon isotope profile of animal tissues resembles that of the food taking into account a fractionation of about 1‰ per trophic level. Thus, for food sources differing in carbon isotope profile, the isotopic composition of the tissue may ideally indicate the relative contribution of each source to the diet. With respect to nitrogen, animals are usually enriched in ^{15}N (about 3‰) relative to the diet (Michener & Schell 1994).

The purpose of this study was to provide some preliminary information on diet characteristics of these species and to serve as a possible starting point for more detailed analyses.

MATERIALS AND METHODS

The samples analyzed were collected on different occasions; however, all samples were taken during the south-west monsoon (July–September) at the island of Phuket, Thailand. Gut contents analysis was performed on a sample (Sample 1) of snails collected on *R. apiculata* mangroves at Chalong Bay and dropped into 70% ethanol (five individuals of each species were analyzed). Another sample (Sample 2) was collected on *Avicennia marina* (*L. scabra* and *L. intermedia*) at Tang Khen Bay and *Rhizophora* (*L. pallescens*) at Chalong Bay and fixed in 70% ethanol after cracking the shell (10 individuals of each species). The contents of the stomachs were removed under a dissecting microscope, smeared onto microscope slides, and imbedded in glycerol gelatin. From each snail three smears were prepared, and from each smear three fields were scored by ocular grid (81 intersections per field). Objects at each intersection were classified (i.e., 729 scores per individual).

Snails were collected for carbon and nitrogen stable isotope analysis from *R. apiculata* mangroves at Chalong Bay and kept cool for 3 days in plastic containers during transport to Denmark

*Corresponding author.

before being frozen. For analysis the soft tissue was separated from the shell and operculum and lyophilized prior to being ground with a mortar and pestle. Prior to analysis the tissue was acidified (10% HCl) to ensure the removal of any carbonate debris, rinsed with distilled water, and then freeze-dried again. Analysis of carbon and nitrogen isotopes was also performed on stomach contents removed from snails that had been fixed in 70% ethanol (Sample 1), but only nitrogen results are presented.

Potential food sources were collected from *R. apiculata* mangroves at Chalong Bay. *Rhizophora* leaves were picked from trees, dried at 60°C, and ground for stable isotope analysis. Leaf surfaces were also carefully scraped with a surgical blade without damaging the epidermis. Scrapings from about 50 leaves were pooled in each sample and dried at 60°C before analysis. Wetted surfaces of prop roots and stems were lightly scraped with surgical blades. These scrapings were taken from random spots distributed within the range occupied by the snails, and the obtained material was shaken in a bottle with distilled water and filtered through 250-μm and 63-μm filters and finally onto pre-combusted Whatman GF/C-filters (Whatman Intl. Ltd., Maidstone, UK). The three fractions were dried at 60°C along with nonfractionated scrapings. Particulate organic matter (POM) was filtered from the waters of the bay onto precombusted Whatman GF/C filters and dried at 60°C.

Samples were prepared and analyzed as reported by Handley et al. (1991, 1993). The mass spectrometric analyses were done on a Europa 20-20 IRMS with an ANCA-SL sample converter (PDZ Europa, Cheshire, UK). A routine precision of approximately 0.1‰ for both C and N for invertebrate samples have been obtained. Stable isotope ratios are reported in standard δ notation as $\delta I = [(R_{sample}/R_{standard}) - 1] \times 1{,}000$, in units of per mil, where I is the element in question, and R is the ratio of the heavy to the light isotope. Standards were a CO_2-C standard previously calibrated against the universal Pee Dee Belemnite standard and atmospheric nitrogen.

RESULTS

The three *Littoraria* species exhibited clear differences in composition of the stomach contents with respect to identifiable components (Fig. 1). However, the major part of the stomach contents could not be identified microscopically. Cork cells from mangroves contributed significantly to the stomach contents of *L. scabra* and was also the dominant identifiable item in the stomachs of *L. intermedia*. In *L. pallescens*, fungal hyphae and spores were the most prominent identifiable objects, but these items were also present in the other two species. Diatoms, other algae, and cyanobacteria were present in all species, but only in *L. scabra* and *L. intermedia* could algae in any significant amounts be identified. Kruskal-Wallis tests revealed significant differences among species for all food items except diatoms (Sample 2): hyphae: $K = 15.8$, $P < 0.001$; spores: $K = 21.3$, $P < 0.001$; other algae: $K = 10.9$, $P = 0.004$; cork cells: $K = 19.1$, $P < 0.001$ (d.f. = 2 in all cases).

Stomach contents from snails that had the shell cracked had a higher diversity of identifiable items than snails that had been dropped directly into 70% ethanol, but also in the latter (Sample 1) were there clear differences between species, with cork cells being most prominent in *L. scabra* and fungal hyphae most prominent in *L. pallescens*.

Isotopic signatures of the soft tissue of the three *Littoraria* species exhibited considerable individual variation (Fig. 2). In *L. scabra* the mean $\delta^{13}C$ value was −24.22‰, and the range was −26.34 to −22.67‰ ($n = 16$). *L. intermedia* had a mean $\delta^{13}C$ of −22.51‰ and a range of −24.82 to −20.21‰ ($n = 16$), and *L. pallescens* had a mean $\delta^{13}C$ of −22.45‰ and a range of −24.86 to −17.27‰ ($n = 15$). A Kruskal-Wallis test revealed significant differences among species ($K = 9.21$; $P = 0.01$; d.f. = 2), with *L. scabra* being significantly more ^{13}C depleted than the other two species. Also, nitrogen isotopic signatures of the three snail species were highly variable. *L. scabra* had a mean $\delta^{15}N$ of 1.89‰ and a range of −4.64 to 6.11‰ ($n = 16$). *L. intermedia* had a mean $\delta^{15}N$ value 1.43‰ and a range of −6.97 to 6.80‰ ($n = 16$), and *L. pallescens* had a mean $\delta^{15}N$ of −1.80‰ and a range of −6.12 to 2.00‰ ($n = 15$). Differences among species were significant ($K = 9.42$; $P < 0.01$; d.f. = 2), and *L. pallescens* was significantly more ^{15}N depleted than *L. scabra* and *L. intermedia*; the latter showed the largest individual variation.

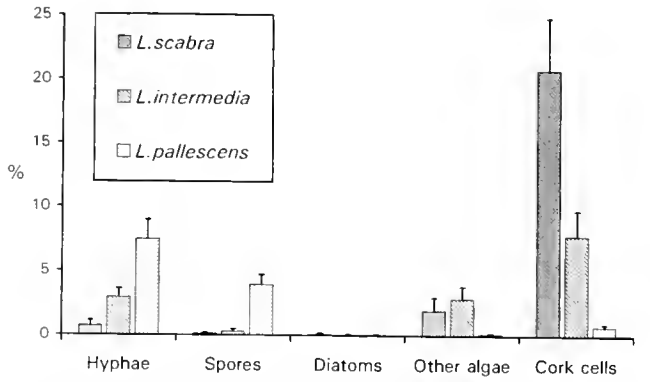

Figure 1. The occurrence of identifiable items in stomachs of three *Littoraria* species expressed as percentages (mean + standard error) of the total number of objects observed under an ocular grid in microscopic smears. Items include fungal hyphae and spores, diatoms, other algae (including cyanobacteria), and cork cells from mangroves. Animals fixed in 70% ethanol after cracking of the shell (Sample 2). *Littoraria pallescens* collected on *Rhizophora apiculata*; *L. scabra* and *L. intermedia* collected on *Avicennia marina*.

Isotope analyses performed on stomach contents of snails fixed in 70% ethanol resulted in a mean $\delta^{15}N$ of 1.33‰ (0.22 to 3.52‰; $n = 7$) in *L. scabra*, a mean $\delta^{15}N$ of 2.38‰ (−1.91 to 7.31‰; $n = 9$) in *L. intermedia*, and a mean $\delta^{15}N$ of −1.24‰ (−2.91 to −0.19‰; $n = 9$) in *L. pallescens*. Again, *L. pallescens* was the most ^{15}N depleted, and *L. intermedia* was the most variable of the species.

Rhizophora leaves, scrapings from both leaf and prop-root surfaces, and local POM were well separated on the basis of their $\delta^{13}C$ and $\delta^{15}N$ signatures (Fig. 2). POM was the least ^{13}C depleted of the sources, and *Rhizophora* leaves, leaf scrapings, and the >250-μm fraction of the prop-root scrapings were the most depleted. Leaf scrapings were highly depleted in ^{15}N compared with the other sources. A few of the *L. scabra* and *L. intermedia* individuals had $\delta^{15}N$ values consistent with a diet of mixed mangrove and POM, whereas the remaining *L. scabra* and *L. intermedia* and all the *L. pallescens* were too ^{15}N depleted.

DISCUSSION

Although only small amounts of the stomach contents could be identified, the differences among species with respect to the identifiable fraction of the diet appear to reflect true differences in diet. Whether the differences are solely a result of differences in com-

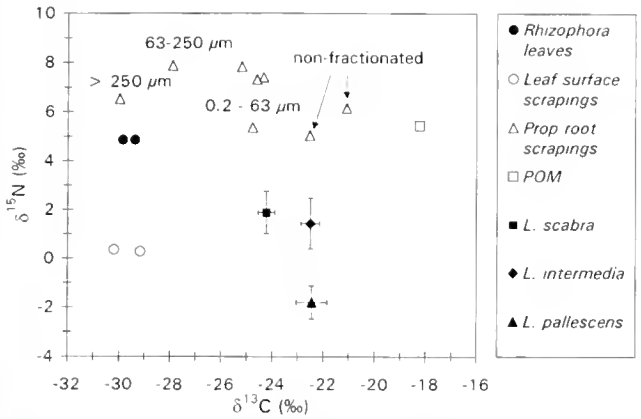

Figure 2. Stable isotopic carbon and nitrogen signatures of the soft tissue of three species of *Littoraria* collected on *Rhizophora apiculata* (means ± standard error of means) and of some potential sources of food for these snails presented as individual sample measurements.

position of the substrates upon which the snails feed (i.e., a result of zonation) or of the snails' ability to actively select among available items cannot be discerned on the basis of available data. Neither can the extent to which different items contribute to assimilated matter in the three species. Cork cells, fungal hyphae, and spores are major identifiable structural components of the diet, but whether they contribute significantly to the snails' energy budget is unknown. Fungal material in the diet was also reported by Kohlmeyer and Bebout (1986) in *L. angulifera* and by Newell and Bärlocher (1993) in *L. irrorata*.

The difference between snails that had their shells cracked prior to fixing and those fixed whole with respect to diversity of items is probably a result of continued breakdown of easily degradable food items in those snails dropped whole into ethanol. This underlines the importance of rapid and effective fixing of material for stomach analysis. The diet analyses demonstrate that there are differences between species as far as structural components in the gut contents are concerned, but these differences should not be overinterpreted because only a fraction of the gut contents can be identified.

The considerable overlap and scatter in isotope ratio values suggest that the snails are opportunistic feeders and that they to some extent share food resources. The wide range of *Littoraria* $\delta^{13}C$ values (−26.3 to 17.3‰) suggest carbon assimilation from multiple sources (epiphytes from leaves and prop roots, deposited POM, and *Rhizophora* detritus). *L. intermedia* and *L. pallescens*, the smallest species, had identical mean $\delta^{13}C$ values, whereas *L. scabra* was significantly more ^{13}C depleted. A diet of microalgae and cork cells from prop roots could explain this pattern with *L. scabra*, which is larger and consumes relatively more cork cells. However, all three species were on average more ^{15}N depleted than these food sources. *L. pallescens* had a significantly lower mean $\delta^{15}N$ value than the other two species, and it is clear that it does not derive its food directly from the mangrove leaves upon which it lives. It must derive a significant amount of its food from a strongly ^{15}N-depleted source. Such a source was present in scrapings from leaf surfaces ($\delta^{15}N = 0.3 \pm 0.05$‰; $n = 2$), but it is as yet unknown what it represents and how it is related to the diet of the snail.

Rodelli et al. (1984) reported stable carbon isotope ratios in plants and animals from Malaysian mangrove forests. They found a $\delta^{13}C$ of −27.2‰ in *R. apiculata*, which is acceptably close to our value of −29.6‰ ($n = 2$). In *L. melanostoma* they found a $\delta^{13}C$ of −24.6‰ (mean of 3) comparable to that of *L. scabra* in our study, and a value of −21.5 (mean of 10) in *L. undulata* (a rock-dwelling species). They did not report nitrogen isotope ratios.

L. irrorata in a North Carolina salt marsh had $\delta^{13}C$ values of −16.6 to −15.1‰ and $\delta^{15}N$ values of 2.2 to 3.7‰ (diet 0.1 to 3.8‰) (Currin et al. 1995), and in a Kenya mangrove forest the herbivorous snail *Terebralia palustris* had a $\delta^{13}C$ value of −24.23‰, similar to that of its presumed mangrove leaf diet ($\delta^{13}C = -24.28$‰), and a $\delta^{15}N$ signal consistent with the normal pattern of enrichment relative to the diet (Marguillier et al. 1997). If we assume that the on average very depleted ^{15}N signatures of the studied *Littoraria* tissues are not in conflict with the generally observed 3‰ enrichment per trophic level in animals (Owens 1987, Michener & Schell 1994), we must conclude that all of the three *Littoraria* species have assimilated a yet unknown and very ^{15}N-depleted food source, but other unknown fractionation processes may be involved.

The fact that the snails were kept alive for 3 days before being frozen could be invoked as a source of ^{15}N depletion. However, it is difficult to identify a mechanism leading to this result. First of all, such a mechanism should affect individuals differently because not all individuals were highly depleted. Furthermore, starvation is known to lead to ^{15}N enrichment of the tissues (e.g., Hobson et al. 1993), and, finally, stomach contents had equally ^{15}N-depleted signatures, again with *L. pallescens* being on average the most depleted. The ^{15}N signatures of stomach contents were obtained from snails that were killed without delay by dropping them into 70%ethanol, a procedure that is expected not to affect nitrogen isotope ratios. Mangrove snails may stay inactive for days during dry periods, so being deprived of food for 3 days is not entirely unnatural for them.

A purely hypothetical scenario explaining the ^{15}N depletion is that nitrogen excreted by the snails (uric acid) is recycled (e.g., through fungi), involving fractionation (depletion), and that the fungi subsequently are ingested by the snails. Supporting such a hypothesis is the fact that excretion products (ammonia, urea, and uric acid) are depleted compared with the dietary source and the tissues of the animals excreting them (Gannes et al. 1997) and that fungi are most prominent in the diet of the most ^{15}N-depleted species (*L. pallescens*). Fungi are among the microorganisms known to degrade uric acid (Kieslich 1976). Microorganisms like the cyanobacterium *Anabaena* grown on nitrate or ammonia show large fractionations and ^{15}N depletions (Macko et al. 1987).

The results underline the usefulness of multiple isotope analyses. A more limited conclusion would have been reached had the analysis been based on gut contents and stable carbon isotopes alone. The wide range of isotope ratios within species further stresses the importance of large samples in food chain studies. Considerable bias or loss of information may result if one attempts to deduce trophic relationships based on pooled samples of three or four individuals. During the last three decades, most isotopic studies have been based on small samples under the assumption that there is insignificant variation between individuals within species. Our data demonstrate that this is not always the case and that variation can be large, possibly due to small-scale heterogeneity in the occurrence and accessibility of food items. Detailed studies are needed to explain the highly ^{15}N-depleted tissues and the range of variation in N isotope ratios in these snails.

ACKNOWLEDGMENTS

We wish to thank the director of the Phuket Marine Biological Center, Thailand, Dr. Prawin Limpsaichol, and Mr. Somchai Bussarawit for the opportunity to work at the laboratory. Dr. C.-K. Kang prepared all the samples (decalcification and weighing) and did some initial mass spectrometric analyses while Dr. C. M. Scrimgeour of Dundee University, Scotland, performed the final mass spectrometric analyses on our samples. We also thank two anonymous reviewers for valuable criticism.

SHELL SIZE VARIATION IN *LITTORINA LITTOREA* IN THE WESTERN SCHELDT ESTUARY

HANS DE WOLF,[1]* RONNY BLUST,[1] AND THIERRY BACKELJAU[1,2]

[1]*University of Antwerp (RUCA), Groenenborgerlaan 171 B-2020, Antwerp, Belgium;* [2]*Royal Belgian Institute of Natural Sciences (KBIN), Vautierstraat 29, B-1000, Brussels, Belgium*

ABSTRACT *Littorina littorea* was collected along a salinity gradient in the Scheldt estuary, located in the South of the Netherlands. Its morphological population structure was investigated to see whether salinity was correlated with shell size and shell weight. Shell size did not increase along the salinity gradient, as was expected, but rather showed a clear size transition between two salinity ranges (i.e., 10–20‰ and 21–30‰). Animals attain their largest size within a salinity range of 21–30‰. Relative shell weight did not vary consistently with salinity.

KEY WORDS: environmental stress, estuary, *Littorina littorea*, salinity, Scheldt river, shell size

INTRODUCTION

Although littorinids show high levels of intraspecific shell polymorphisms (see Reid 1996 and references therein), *Littorina littorea* (Linnaeus, 1758), the largest species in the genus, shows relatively little morphological variation (Janson 1987). However, morphological differences were noted between populations of *L. littorea* on the West Somerset coast (Crothers 1992). Along this coastline, a weak correlation was found between shell shape, as expressed by the shell length/aperture length ratio, and wave exposure (Crothers 1992). The differences were explained by differential growth and/or survival rates in response to the effects of wave exposure (Crothers 1992). In contrast, Janson (1987) found almost identical shapes between exposed rocky and boulder shore specimens. Apparently, the only consistent shell variation is found between marine and sheltered brackish forms, with the latter being smaller and thinner-walled (see Reid 1996). This variation is supposed to be ecophenotypic (Reid 1996) because *L. littorea* is a planktonic developing animal that is presumed to have a high dispersal and gene flow potential (Janson 1987, Reid 1996), minimizing the likelihood of selection as a possible impetus for the observed shell variation (Chapman 1995). Nevertheless, predation experiments with the oystercatcher *Haematopus ostralegus* have shown that the aperture size of *L. littorea* may be susceptible to selection, although field observations have never confirmed these experimental results (Robertson 1992).

L. littorea is widely distributed, occurring in the eastern (White Sea to southern Portugal) and western (Labrador to Virginia) Atlantic (Reid 1996). Unlike other littorinids, it does not solely occur on hard substrates but is also able to crawl over sand and soft mud (references in Reid 1996). This ability, along with its planktonic development and its tolerance to low salinity conditions (9.5‰), enables it to penetrate far into estuaries (Reid 1996).

In the Scheldt estuary, situated in the south of The Netherlands, *L. littorea* is found from Vlissingen (i.e., rivers' mouth) to Bath, 50 km inward from the mouth, where it occurs along a gradually decreasing salinity gradient, ranging from marine to brackish (Fig. 1). The Scheldt estuary thus forms an ideal setting to test whether salinity is indeed correlated with the shell morphology of *L. littorea*. If, under brackish conditions, *L. littorea* has a smaller, thinner-walled shell, then we expect a shell-size, weight gradient in the estuary following the salinity gradient.

MATERIALS AND METHODS

On 8 August 1998, *L. littorea* was collected at seven sites along the western Scheldt estuary, covering its entire range in the western Sheldt (Fig. 1). These sites included, in order of increasing salinity: Bath, Waarde, Hansweert, Hoedekenskerke, Ellewoutsdijk, Borssele, and Vlissingen (Fig. 1). One population was collected at each site. Each sample consisted of 40 animals. Each of the 280 specimens was morphometrically characterized. Five shell traits were measured to the nearest 0.05 mm using a caliper: shell height (HS), shell width, aperture height, aperture width, and shell-top height (De Wolf et al. 1997). In addition, total wet weight (i.e., shell + soft body parts) and body wet weight (soft body parts) were determined to the nearest mg, and all individuals were sexed on the basis of the presence or absence of a penis.

A seven-by-two contingency table was constructed to test whether the sex distribution differed from site to site, employing the Metropolis algorithm to obtain unbiased estimates of the exact *P* value (Miller 1997). Morphometric patterns were investigated by means of a two-way multivariate analysis of variance (MANOVA), contrasting the fixed factor "sex" with the random factor "sampling site." Morphological patterns were further investigated by means of a standard canonical discriminant analysis (CDA). Finally, an analysis of covariance (ANCOVA) of shell weight was performed using shell height as a covariate. Of special interest in this analysis is the interaction with the covariate because it tests whether the slopes of the shell weight on shell length are homogenous for the seven sites. Except for the contingency table analysis, all statistical analyses were performed using the software package Statistica v. 5.0 (Statsoft 1995).

RESULTS

At each site, except for Hoedekenskerke, males outnumbered females (Fig. 1). The number of males differed significantly at the different sites ($P = 0.0003$). The results of the two-way MANOVA are summarized in Table 1. A significant part of the total variation can be explained by the random factor "sampling site" (Table 1), whereas the fixed factor "sex" did not contribute significantly, nor did the interaction (Table 1)

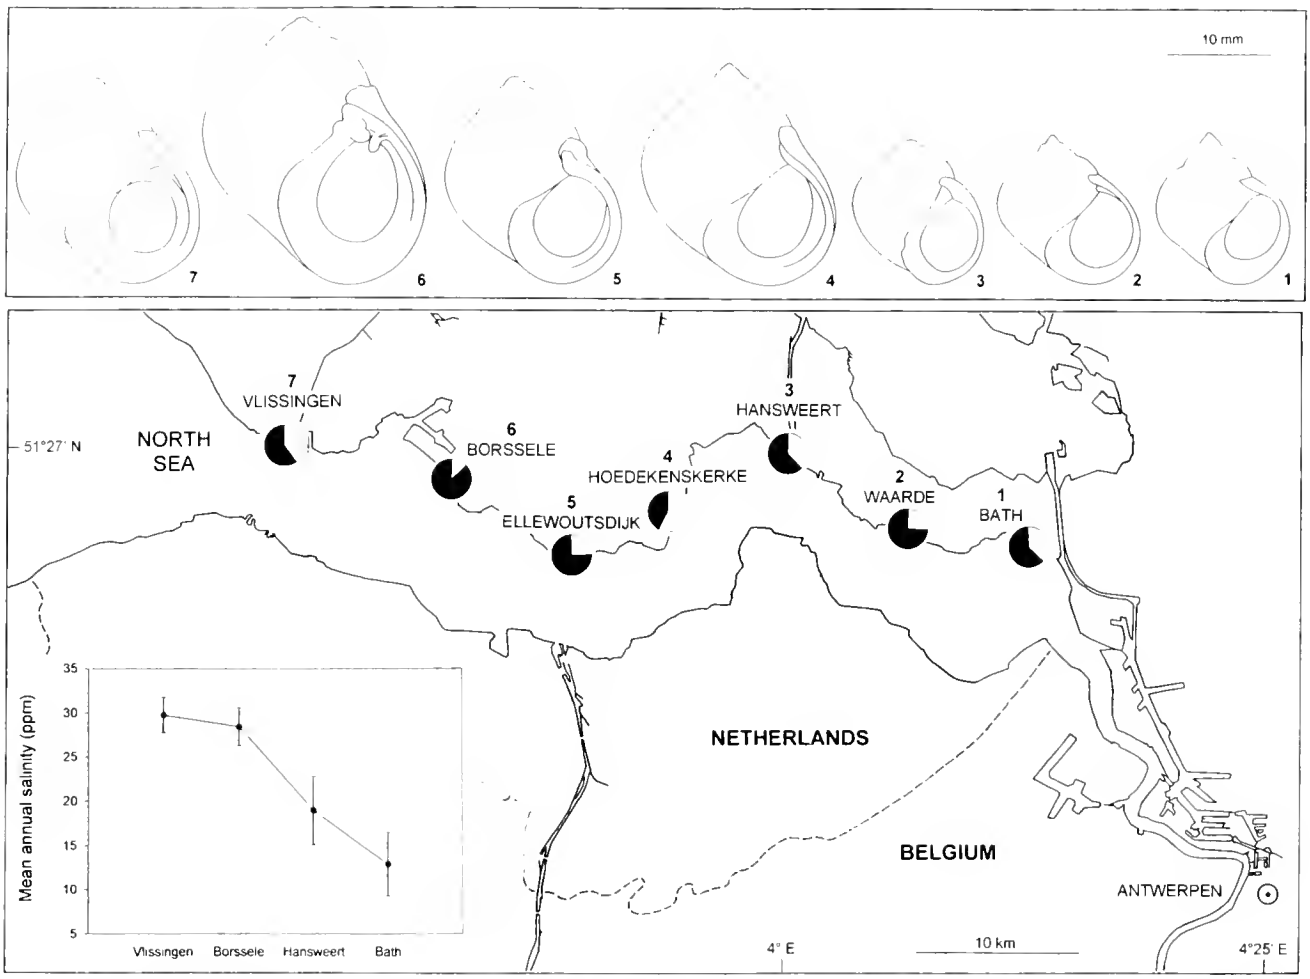

Figure 1. Sampling area, sites, and shells typical of each of the sampling sites (sites 1–7). Pie diagrams represent number of males (black zone) and females (white zone) collected at each site (n = 40). The line graph represents mean salinity values and standard deviations along the Scheldt estuary on the basis of seasonal measurements from 1990-1997.

These results are illustrated in Figure 2, where the mean shell height and standard deviations for males and females are plotted for each sampling site. Mean shell height values for both sexes overlap but simultaneously reveal a structuring at the sampling site level. Mean shell height of specimens collected at the less marine-like sites (i.e., salinity range 10–20‰: Fig. 1) are on average smaller compared with the shell height of specimens collected more downstream at a salinity range of 21–30‰ (Fig. 1). However, due to individual variation this observation is merely a trend because post-hoc Sheffé tests failed to significantly discriminate both groups.

Given that, with respect to the measured shell characteristics, males do not differ significantly from females, a single CDA was performed without considering the factor "sex." The mean values of the first two canonical variables (CV) are used to plot all sampling sites, as shown in Figure 3. The first CV describes 64.83% of the total variation and is mainly an expression of shell height (Table 2; HS = −1.11614). Shell height decreases with decreasing CV1 values, discriminating the different sampling sites, so that specimens collected at the least marine-like sampling sites are in general smaller than specimens collected at more marine-like sites (Fig. 3). The second CV describes an additional 19.83% of the total variation and is mainly an expression of the shell weight (Table 2; SW = 1.91514). Shell weight increases along the positive CV2 axis. Four groups can be distinguished along both CV axes: Bath and Waarde, consisting of specimens with small and light shells; Hansweert, consisting of specimens with small and relatively heavy shells; Ellewoutsdijk and Vlissingen, consisting of specimens with intermediate-sized shells and intermediate shell weights, and Borssele and Hoedekenskerke, consisting of specimens with larger and heavier shells. Hence, relative shell weight does not follow the salinity gradient. This is also illustrated in the ANCOVA, where the regression slopes of the shell weight on shell height are not homogeneous at the different sampling sites (Table

DISCUSSION

As was predicted, *L. littorea* had smaller and lighter shells in more brackish conditions. However, shell size did not decrease clinally away from the sea, following the salinity gradient. Instead, specimens were either small (approximately <15 mm) or large (approximately >19 mm). No intermediate-sized animals were found at sites having intermediate salinity levels (i.e., ±15‰). If salinity is indeed an environmental factor that affects shell size in *L. littorea*, it seems that its effect is either present or absent with a threshold salinity value of approximately 15–20‰. Above this salinity threshold, animals are able to attain a large shell; below this value, animals never have comparable shell sizes. In either case it must be clear that, at brackish sites, *L. littorea* is likely to encounter less favorable living conditions, which might result in a decrease of growth and/or survival rate (Crothers 1992), shifting the less marine-like populations toward smaller-sized individuals. It must also be noted, however, that the largest shells were not recorded at Vlissingen (i.e., highest salinity) but at Borssele (i.e., second highest salinity). At Borssele, specimens were collected in the direct vicinity of a nuclear power plant. Possible water temperature differences, due to the outflowing cooling water, might affect the species shell growth. Indeed, larger shells can be produced at higher temperatures due to the lower energy cost of calcification because calcium carbonate dissolves less well at higher temperatures (Graus 1974, Clarke 1983). However, on a macrogeographical scale, *L. littorea* attains its largest size in the northern parts of its distribution range (i.e., cooler waters) (Reid 1996). Clearly, further experimental work is needed to clarify and explain the possible effects of water temperature and salinity on shell deposition in *L. littorea*.

In the case of shell weight, the presumed relationship with salinity was even less clear. Moreover, it seemed unlikely that relative shell weight differences can be explained by salinity differences. The top right positioning of the Hansweert population in the CDA graph (Fig. 3) indicates that specimens with the highest relative shell weight occur under the third lowest salinity conditions.

Abbreviations: SS = Sum of squares; MS = Mean square.

Sexual dimorphism is common in the genus *Littorina*, with females being larger than males (Reid 1996), which is presumed to be related to growth and/or longevity differences (Reid 1996). However, sex-related shell height differences have not been found in *L. littorea* (Reid 1996), even though sexual selection for female shell size has been documented, with males preferring to mate with larger, and thus more fecund, females (Erlandson & Johannesson 1994). The fact that we did not find sex-related shell size differences is thus in agreement with what was previously found. However, our sex assignment, made on the basis of the presence or absence of a penis, leads to a sex ratio of almost 2:1 (male/female), which differs markedly from a previously published sex ratio of 1:1 (Daguzan 1977). The fact that we found twice as many males might be related to the presence of imposex—the development of male sex characteristics on females (e.g., a penis and/or vas deferens) (Bauer et al. 1997)—and/or intersex—the disturbance of the phenotypic sex determination between the gonad and genital tract—which is known to occur in *L. littorea* (Bauer et al. 1997). Imposex has never been recorded in *L. littorea*. In contrast, intersex gradually transforms the female pallial tract such that the female pallial organs are supplanted by a male prostate gland, and a seminal groove and a small penis occur (Bauer et al. 1997). The fact that penis shedding and/or regression also occur in *L. littorea* (Deutsh & Fioroni 1992) makes it even more difficult to distinguish between an intersex female and a male with a shed or regressed penis. Therefore, it could be that some specimens that were classified as males were in fact intersex females. However, female intersex expression occurs only in juvenile stages or during sexual immaturity (Bauer et al. 1997). As a consequence, intersex females are expected to have a smaller shell. Hence, if intersex females were included in the male population, they would not have increased the mean male shell height, masking possible shell size differences with the presumed larger females, but rather would have decreased the mean shell height of the male population. In any event, the occurrence of penis shedding, penis regression, and intersex make basing sex assignment in *L. littorea* on the presence of a penis unreliable. Similarly, the presence or absence of a prostate gland is also an unreliable sex-determining character (Bauer et al. 1997).

Finally, salinity is not the only environmental factor that may be correlated with the morphology of *L. littorea*. In an estuary, which is structured by a complex of gradients, a wide variety of natural and human-induced stresses are present that may affect the shell morphology of estuarine gastropods. In this respect, in the period 1981 to 1983, the Scheldt estuary was ranked among the most heavily polluted estuaries around the world for both the dissolved as well as the particulate metal phase (Bayens 1998). Dissolved metal concentrations measured at Hansweert and Vlissingen differ significantly, with Vlissingen being less polluted (Rijksinstituut voor Kust en Zee, RIKZ, pers. comm.). Concentrations of volatile organic compounds are high and decrease along the estuary as well (De Wulf et al. 1998). Clearly, pollution is an important potential stressor in the Scheldt estuary, and its effect on the morphological population structure of the estuarine organisms must be investigated.

ACKNOWLEDGMENTS

The authors would like to thank Gilles Watel (RIKZ) for kindly providing us with the salinity and dissolved heavy metal measurements taken in the western Scheldt. Peter Mill and an anonymous referee improved this manuscript greatly. This research was supported by a RAFO project under the contract number RAFO/1 DEWOH KP98. HDW is a Postdoctoral Fellow of the Fund for Scientific Research - Flanders (Belgium) (F.W.O.).

CARBONATE PROCESSING BY INTERTIDAL GASTROPODA ON JAMAICAN LIMESTONE SHORES

ALLUWEE DOBSON-MOORE AND JOSEPH C. BRITTON*
Department of Biology, Texas Christian University, Fort Worth, Texas 76129

ABSTRACT At least eight species of Littorinidae occur sympatrically on a limestone platform on the northern coast of Jamaica with little evidence of competitive displacement. Most of these, plus a cobble shore gastropod (*Planaxis nucleus*), were studied with respect to the amount of carbonate each removes from the shore while feeding. The feces of *P. nucleus* contain 92.8% carbonate. On the platform, *Nodilittorina riisei* fecal pellets contained 88.7% carbonate, *N. ziczac* 74.9%, *N. angustior* 67.0%, *N. dilatata* 88.3%, *Tectarius antonii* 91.3%, *Cenchritis muricatus* collected from the rocky substratum 74.8%, and *C. muricatus* collected from the maritime shrub *Rhachicallis americana* 18.6%. Although the rock-dwelling Littorinidae ingest different quantities of carbonate, there is no clear relationship between the amount of carbonate ingested and the position each species occupies on shore. Fecal pellet counts were made for all species. The mean numbers of pellets recovered from the rectums were: *P. nucleus* (48.7), *N. riisei* (8.56), *N. ziczac* (26.1), *N. angustior* (14.1), *N. dilatata* (22.2), *T. antonii* (22.8), and *C. muricatus* (35.3). The mean size and weight of pellets for each species were: *P. nucleus* (1.73 mm^2, 0.040 mg), *N. riisei* (1.21 mm^2, 0.028 mg), *N. ziczac* (1.43 mm^2, 0.066 mg), *N. angustior* (0.959 mm^2, 0.024 mg), *N. dilatata* (1.76 mm^2, 0.052 mg), *T. antonii* (3.23 mm^2, 0.118 mg), and *C. muricatus* (4.45 mm^2, 0.112 mg). The bioerosive impact of each species was assessed by calculating the amount of carbonate removed from the shore per individual and per species based on density and an estimated 48-h defecation cycle. Impacts were expressed in terms of both a single defecation cycle and annually. Collectively, the Littorinidae are estimated to remove at least 2,850 kg of carbonate from the approximately 500 × 24-m limestone platform annually.

KEY WORDS: *Littorinidae*, fecal pellets, carbonate, rocky shore, Jamaica

INTRODUCTION

At least eight species of Littorinidae (Lang et al. 1998, Minton & Gochfeld 2001) occupy a limestone platform on the northern coast of Jamaica, from near sea level to as much as 4 m above it. Most of them (except the tidepool-dwelling *Nodilittorina mespelum*) occupy very similar niches in broadly overlapping ranges from the splash zone to as much as 30 m inland from the sea, with little evidence of competitive displacement. Several previous studies have attempted to elucidate the roles of biotic and abiotic factors in controlling the distribution of sympatric littorinid species on hard-shore habitats, mostly with inconclusive results. Britton (1992) showed that the resistance to evaporative water loss and tolerance to thermal stress had little correlation to the position on the shore occupied by each species. He suggested, however, that dessication tolerance may be a more important limiting factor than thermal stress in dictating species position on shore. Lang (1995) found that shell sculpture and spire height in three littorinid species were unrelated to shore position and shell nodulosity. The presence of nodules on shells is widely assumed to confer a temperature regulatory advantage (Vermeij 1973); however, they could not be shown to do so. In a comprehensive survey of several ecological parameters associated with Jamaican rocky-shore littorinids, including position and direction of repose, substratum and body temperatures, nature of attachment to the substratum, microhabitat (within crevices or not), and availability of moisture in association with the substratum, Lang et al. (1998) found few significant correlations between these parameters and the positions species occupy on the shore. Furthermore, there were few species-specific differences for most of the parameters examined. Substratum moisture, however, was modestly predictive of which species might be expected on a portion of the shore, with *N. riisei* always occupying wetted surfaces at the seaward face of the platform, *Cenchritis muricatus* always on the highest and driest areas at the back of the platform, and the other species at various, broadly overlapping positions in between.

Location on a shore is an important factor in determining the degree of stress a species will encounter, ranging from thermal and dessication exposure to what foods are available to the species (McMahon 1990, Norton et al. 1990, McMahon & Britton 1991). On the Jamaican platform shore, *N. riisei* (Mörch, 1876), *N. ziczac* (Gmelin, 1791), and *N. angustior* (Mörch, 1876) occupy the upper eulittoral zone, although the latter may also range into the lower supralittoral fringe. *N. dilatata* (d'Orbigny, 1846) and *Tectarius antonii* (Philippi, 1846) have a broad distribution across the mid- to lower supralittoral fringe, whereas *C. muricatus* (Linnaeus, 1758) preferentially occupies the upper supralittoral to the margin of maritime vegetation (Lewis 1960, Bandel 1974a, Lang et al. 1998). *Planaxis nucleus* (Bruguière, 1789) (Prosobranchia: Planaxidae), the only nonlittorinid examined in this study, does not occur on the platform but is found instead on large immobile limestone boulders awash in surf on a nearby cobble shore, identified locally as Jingle Beach.

The Littorinidae are predominantly herbivorous gastropods that rasp the substratum for food by means of a radula (Reid 1989, Norton et al. 1990). On the Jamaican rocky shore, there are differences in the quantity and quality of food sources from the splash zone to the highest parts of the limestone platform. It seems plausible, therefore, that the herbivores occupying different vertical zones have different food preferences. Low-zoned species such as *N. riisei*, in the presence of abundant moisture and epilithic algae, might rely less upon potentially harder-to-reach endolithic cyanobacteria. In contrast, the high-zoned *T. antonii*, living exclusively on rock, has little opportunity to feed upon epilithic or epiphytic algae. The higher-zoned *C. muricatus* may graze upon the stems and leaves of maritime vegetation, but when on rock, it, like *T. antonii*, must focus instead on a diet of endolithic algae and/or lichens. Peckol and Guarnagia (1989) showed that the gut of *T.*

antonii contains considerable amounts of endolithic cyanobacteria, which occur abundantly throughout the vertical range of this species. We will show that *C. muricatus* has an alternate food source among the maritime angiosperm vegetation.

In this study, we hypothesize that diet may reflect one aspect of resource partitioning among intertidal gastropods. Rock-dwelling species that must rely heavily upon endolithic algae for food (e.g., *C. muricatus* and *T. antonii*) should also have a large quantity of non-nutritious calcium carbonate in the feces. Conversely, species living among epilithic algae (e.g., *N. riisei* and *N. ziczac*) may focus on this more easily obtained food when it is available. If so, the fecal carbonate fraction should be much less than that associated with the high-zoned species.

Members of the Littorinidae and Planaxidae are ideal models for an analysis of fecal content because they form the feces into discrete, compact, and relatively glutinous pellets that are retained in a discrete rectum until eliminated from the body. Fecal pellets of the Jamaican rocky shore Littorinidae have a similar morphology, mostly ranging from ovoid to drop-shape. They contrast sharply with the narrow, spindle-shaped pellets of the Planaxidae (Bandel 1974b). The pellets of those species living on rocky surfaces consist mainly of fine detritus, including mineral flakes and rock fragments that they scrape from the surface while rasping off algae (Bandel 1974b).

We hypothesize, therefore, that the fecal pellets of different species of herbivorous intertidal Gastropoda contain carbonate in different proportions according to their food choices and/or method of grazing. If such differences can be detected, this might suggest one method by which these species partition resources on this shore. We also assess the bioerosive impact of these species. The number and weight of the fecal pellets per individual as well as measurements of the size of fecal pellets for 50 individuals of each species were used to estimate the amount of carbonate removed from shore by these gastropods.

MATERIALS AND METHODS

Six species of Littorinidae (Gastropoda: Prosobranchia: Littorinidae) were collected from a micro-karsted limestone shore platform near the Hofstra Marine Lab at Priory, St. Ann's Parish, on the northern coast of Jamaica. Lang et al. (1998) described this shore and the distribution of the littorinids on it. *N. dilatata*, *T. antonii*, and *C. muricatus* are mid- to high-zoned nodulose species, whereas *N. ziczac*, *N. angustior*, and *N. riisei* produce relatively smooth, zebra-striped shells and occupy mid- to lower levels of the platform. A seventh species examined for this study, *P. nucleus* (Gastropoda: Prosobranchia: Planaxidae), was collected from large immobile boulders at Jingle Beach, a cobble shore located about 500 m west of the limestone platform.
